To my immediate and extended family, for their love, support, patience, and encouragement. To my friends, mentors, and colleagues, from whom I continue to learn so much. To the faculty and residents, whose great talent and dedication invigorate me. To the authors and editors of this text, in recognition of their knowledge, skill, wisdom, and generosity.

JGA

To my family, friends, and faculty, who better understand the virtues of patience and without whose support I could never achieve anything great! I am very blessed to be surrounded by such amazing souls. Thanks for being part of this success!

EDB

To Mark, Keaton, and Kameron, you are what is most important in my life. Thanks for supporting me in everything I do. To my students and residents, you give me inspiration and motivation, and you never fail to make “work” fun!

JLC

To Karen, Joshua, and Zachary for your love and undying patience with my educational pursuits and being a constant reminder that you are my main thing. To my patients at Charity Hospital, who inspire me to help others. You have taught me best what it means to be a physician. To my students, residents, peer faculty, and especially Keith Van Meter. Thanks for the opportunity to work and learn with all of you.

PMCD

To Derek and Abby, with all my love. Thank you for your support, encouragement, love, and advice—here’s to many, many years of continued adventures.

MAG

To the HAEMR residents and dedicated faculty, who keep me motivated and humble as we perpetuate the cycle of teaching and learning. To my colleagues, who have shared their experience and wisdom to expand the foundation of our field with this text. To my family and friends, who have supported me along the way. To my mother, Harriet, who was always proud and would continue to be so. To my wife, Marianne, and our children, Josh, Emily, and Henry, for their love, patience, and laughter.

ESN
Preface

We hope that this edition of *Emergency Medicine: Clinical Essentials* will cover the core content of the specialty of emergency medicine in a practical and useful way. The style and format are constructed with emergency medicine residents in mind. The table of contents specifically mirrors the key topic areas of emergency medicine. The chapters are written by physicians who provide lucid explanations and make the information clinically relevant. The authors are experts, leading educators on the topic, and particularly talented academicians. The chapter format favors short segments, highly readable prose, and many subheadings. Maximal use of pedagogic tools such as boxes, tables, figures, and algorithms helps summarize and synthesize key themes. This facilitates initial learning and later enables quick references and resetting of the learning, especially when used in the electronic version. This text is constructed to be easy to use on electronic reading devices, recognizing that books have quickly evolved from static print to dynamic, interactive electronic tools.

This book is designed so that it can be part of a curriculum and embedded into a training program. There is probably no way to master this specialty’s huge amount of content other than continuous, deliberate, concentrated study, so this book hopes to make the study easier through straightforward writing and clear tables and figures. It is never easy to learn large amounts of material and stay current with latest treatment guidelines. This text brings both the latest recommendations and succinct explanations. Eventually, throughout the course of a residency, the core information can be covered in its entirety, at least once but usually twice. The residency program’s clinical experiences, case conferences, simulation exercises, and other parts of the curriculum will reinforce themes, teach additional knowledge, assess judgment, and evaluate practical skills. Faculty members can refer to the text to refresh their own knowledge or to use the tables and algorithms for clinical teaching in the emergency department.

This textbook is also intended to be relevant to the practicing physician, from whom society expects the highest level of clinical practice. The next era of clinical physician evaluation will be to assess whether we are practicing according to evidence-based or consensus-based standards. This text emphasizes these areas of practical, applied decision making. It offers explicit, current, and practical recommendations that will be useful for practicing physicians.

Our clinical practice is rapidly changing as diagnostic tools are increasingly incorporated, new therapies applied, and entirely new disorders emerge. Some types of emergencies were unknown a decade ago, such as those related to novel implanted devices, complications of new surgical procedures such as organ transplantation or bariatric surgery, and even fertility treatment. The use of diagnostic testing, whether magnetic resonance imaging, computed tomography, or bedside ultrasound, is changing. Time-dependent therapeutic interventions for resuscitation and even standards of treatment for serious infectious disease have evolved. All these areas and more are covered in the text as core information for the emergency medicine specialist.

In summary, this textbook is well suited as a stand-alone text or a reference tool but also can be used as a component of an emergency medicine residency curriculum. The link to the specialty core content, the readable design, and the content selection is meant to be useful, accessible, and functional, in addition to forward looking as technology transforms our methods of teaching, learning, and evaluation. We are preparing for the electronic future, where this text fits neatly into a world in which reading is done online, a quick retrieval of information is desired, and a screen-friendly format is appreciated. The world will continue to change quickly, and so will this text.

Eric S. Nadel
Contributors

Michael K. Abraham, MD
Clinical Assistant Professor, Department of Emergency Medicine, University of Maryland School of Medicine, Baltimore, Maryland; Attending Physician, Department of Emergency Medicine, Upper Chesapeake Health System, Bel Air, Maryland

Lung Transplant Complications

Fredrick M. Abrahamian, DO, FACEP
Clinical Professor of Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California; Director of Education, Department of Emergency Medicine, Olive View–UCLA Medical Center, Sylmar, California
Infections in the Immunocompromised Host

Mohammed A. Abu Aish, MD, MEID, FRCPC
Pediatric Emergency Medicine Physician, Division of Pediatric Emergency Medicine, British Columbia Children’s Hospital, Vancouver, British Columbia, Canada

Submersion Injuries

Bruce D. Adams, MD, FACEP
Professor of Surgery, Chief, The Center for Emergency Medicine, University of Texas Health Science Center at San Antonio, San Antonio, Texas

Rhabdomyolysis

James G. Adams, MD
Professor and Chair, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine, Northwestern Memorial Hospital, Chicago, Illinois
Preface
Systemic Lupus Erythematosus

Nima Afshar, MD
Assistant Professor of Medicine, University of California, San Francisco, San Francisco, California

Aortic Dissection

James Ahn, MD
Clinical Instructor, Department of Medicine, University of Chicago, Chicago, Illinois

Inflammatory Bowel Disease

Amer Z. Aldeen, MD, FACEP
Assistant Professor, Associate Residency Director, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine, Northwestern Memorial Hospital, Chicago, Illinois

Epidemic Infections in Bioterrorism

Paul J. Allegretti, DO, FACEP, FACOI
Professor and Program Director, Department of Emergency Medicine, Midwestern University, Downers Grove, Illinois; Professor and Program Director, Department of Emergency Medicine, Provident Hospital of Cook County, Chicago, Illinois

Vasculitis Syndromes

Jennifer F. Anders, MD
Assistant Professor, Department of Pediatrics, Johns Hopkins University School of Medicine; Fellowship Program Director, Division of Pediatric Emergency Medicine, Johns Hopkins Children’s Center, Baltimore, Maryland

Pediatric Gynecologic Disorders

Jana L. Anderson, MD
Instructor in Emergency Medicine and Pediatrics, Departments of Emergency Medicine and Pediatrics, Mayo Clinic, Rochester, Minnesota
Child with a Fever

Phillip Andrus, MD, FACEP, RDMS
Assistant Professor of Emergency Medicine, Mount Sinai School of Medicine, New York, New York

Peripheral Nerve Disorders

Christian Arbelaez, MD, MPH
Assistant Residency Director, Harvard Affiliated Emergency Medicine Residency, Department of Emergency Medicine, Brigham and Women’s Hospital; Assistant Professor of Medicine, Harvard Medical School, Boston, Massachusetts

Health Care Disparities and Diversity in Emergency Medicine

Charles B. Arbogast, DO
Chief of Nephrology, William Beaumont Army Medical Center, El Paso, Texas

Rhabdomyolysis

Chandra D. Aubin, MD, RDMS
Assistant Professor, Assistant Residency Director, Department of Emergency Medicine, Washington University School of Medicine, St. Louis, Missouri

Hernias

Jennifer Avegno, MD
Clinical Assistant Professor, Department of Medicine, Section of Emergency Medicine, Louisiana State University Health Sciences Center, New Orleans, Louisiana

Emergency Medical Services and Disaster Medicine

John Bailitz, MD
Emergency Ultrasound Director, Department of Emergency Medicine, John H. Stroger Hospital of Cook County; Assistant Professor, Department of Emergency Medicine, Rush University Medical Center, Chicago, Illinois
Thoracic Trauma

Patricia Baines, MD
Assistant Professor, Medical Director of Forensic Program, Department of Emergency Medicine, Emory University, Atlanta, Georgia

Gastrointestinal Bleeding

Aaron E. Bair, MD
Associate Professor, Department of Emergency Medicine, UC Davis Medical Center, Sacramento, California

Advanced Airway Techniques

Katherine Bakes, MD
Director, Denver Emergency Center for Children; Associate Director, Emergency Department, Denver Health Medical Center, Denver, Colorado; Associate Professor, Department of Emergency Medicine, University of Colorado School of Medicine, Aurora, Colorado

Neonatal Cardiopulmonary Resuscitation
Pediatric Resuscitation
Pediatric Trauma

Aaron N. Barksdale, MD
Assistant Professor, Department of Emergency Medicine, Truman Medical Center/University of Missouri, Kansas City, School of Medicine, Clinical Instructor, Department of Emergency Medicine, Children’s Mercy Hospital/University of Missouri, Kansas City, School of Medicine, Kansas City, Missouri

Allergic Disorders

William G. Barsan, MD
Professor, Department of Emergency Medicine, University of Michigan, Ann Arbor, Michigan

Altered Mental Status and Coma

Erik D. Barton, MD, MBA
Chief of Emergency Medicine, Division of Emergency Medicine, University of Utah Health Care; Associate Professor, University of Utah School of Medicine, Salt Lake City, Utah

Preface

Benjamin S. Bassin, MD
Clinical Instructor, Department of Emergency Medicine, University of Michigan, Ann Arbor, Michigan

Altered Mental Status and Coma
CONTRIBUTORS

Craig G. Bates, MD, FACEP
Attending Emergency Physician, Metrohealth Medical Center, Clinical Assistant Professor of Emergency Medicine, Case Western University School of Medicine, Cleveland, Ohio
Chronic Obstructive Pulmonary Disease

Jamil D. Bayram, MD, MPH, EMDM, MEd
Assistant Professor, Department of Emergency Medicine, Rush University Medical Center, Chicago, Illinois
Gynecologic Infections

Tomer Begaz, MD
Associate Professor, Department of Emergency Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin
Stable Cardiac Disease

Kavita Bhanot, MD
Attending Physician, Department of Emergency Medicine, St. Joseph Mercy Health System, Ann Arbor, Michigan
Evidence-Based Medicine

Kriti Bhatia, MD
Associate Residency Director, Attending Physician, Department of Emergency Medicine, Brigham and Women’s Hospital, Boston, Massachusetts
Eye Emergencies

Paul D. Biddinger, MD
Director of Operations, Department of Emergency Medicine, Massachusetts General Hospital, Director, Emergency Preparedness and Response Exercise Program, Harvard School of Public Health, Boston, Massachusetts
Regulatory and Legal Issues in the Emergency Department

Andra L. Blomkalns, MD
Associate Professor and Vice Chair, Department of Emergency Medicine, University of Cincinnati College of Medicine, Cincinnati, Ohio
Cardiac Imaging and Stress Testing

John M. Boe, MD
Assistant Clinical Professor, Department of Emergency Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Anorectal Disorders

J. Stephen Bohan, MD
Executive Vice Chairman, Department of Emergency Medicine, Brigham and Women’s Hospital; Assistant Professor, Department of Emergency Medicine, Harvard Medical School, Boston, Massachusetts
Leadership and Emergency Medicine

Keith Boniface, MD, RDMG
Associate Professor, Department of Emergency Medicine, George Washington University Medical Center, Washington, District of Columbia
Bowel Obstructions

Laura J. Bontempo, MD
Assistant Professor, Department of Emergency Medicine, Yale University, New Haven, Connecticut
Maxillofacial Disorders

Pierre Borczuk, MD
Associate in Emergency Medicine, Division of Emergency Medicine, Massachusetts General Hospital; Assistant Professor in Medicine, Harvard Medical School, Boston, Massachusetts
Cardiac Valvular Disorders

Keith Borg, MD, PhD
Assistant Professor, Department of Medicine, Division of Emergency Medicine, Medical University of South Carolina, Charleston, South Carolina
Self-Harm and Danger to Others

Nicholas A. Borm, MD
Resident Physician, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Gynecologic Pain and Vaginal Bleeding

Philip Bossart, MD
Professor, Division of Emergency Medicine, University of Utah School of Medicine, Salt Lake City, Utah
Hip and Femur Injuries

Megan Boysen Osborn, MD
Assistant Professor, Department of Emergency Medicine, UC Irvine Healthcare, University of California, Irvine, Orange, California
Potassium

William J. Brady, MD
Professor of Emergency Medicine and Internal Medicine, Chair, Resuscitation Committee, Medical Director, Emergency Preparedness and Response, University of Virginia Health System; Operational Medical Director, Charlottesville—Albemarle Rescue Squad and Albemarle County Fire Rescue; Medical Director, Allianz Global Assistance, Charlottesville, Virginia
Management of Cardiac Arrest and the Post–Cardiac Arrest Syndrome

Jeremy B. Bronzetti, MD
Acting Instructor, Division of Emergency Medicine, University of Washington, Seattle, Washington
Emergency Delivery and Peripartum Emergencies

Bart S. Brown, MD
Attending Emergency Physician, St. Vincent Emergency Physicians, Indianapolis, Indiana
Emergency Biliary Ultrasonography

David F.M. Brown, MD
Vice Chairman, Department of Emergency Medicine, Massachusetts General Hospital; Associate Professor, Division of Emergency Medicine, Harvard Medical School, Boston, Massachusetts
Acute Coronary Syndrome

Sean M. Bryant, MD
Associate Professor, Department of Emergency Medicine, Rush Medical College/John H. Stroger Hospital of Cook County; Assistant Fellowship Director, Toxikos Consortium; Associate Medical Director, Illinois Poison Center, Chicago, Illinois
Antidepressants and Antipsychotics

John H. Burton, MD
Chair and Professor of Emergency Medicine, Department of Emergency Medicine, Carilion Clinic, Roanoke, Virginia
Facial Trauma

Christine Butts, MD
Clinical Assistant Professor, Department of Emergency Medicine, Director of Division of Emergency Ultrasound, Louisiana State University Health Sciences Center, New Orleans, Louisiana
Emergency Cardiac Ultrasound: Evaluation for Pericardial Effusion and Cardiac Activity
Ultrasound-Guided Vascular Access
Sonography for Trauma
Aortic Ultrasound
Basic Emergency Ultrasound

Mark W. Byrne, MD
Emergency Ultrasound Fellow, Department of Emergency Medicine, Brigham and Women’s Hospital, Boston, Massachusetts
Emergency Renal Ultrasonography

Daniel Cabrera, MD
Assistant Professor, Department of Emergency Medicine, Mayo Clinic, Rochester, Minnesota
Management of Emergencies Related to Implantable Cardiac Devices

Robert D. Cannon, DO
Assistant Professor, Department of Medicine, University of South Florida College of Medicine; Assistant Residency Director, Department of Emergency Medicine, Lehigh Valley Health Network, Allentown, Pennsylvania
Insecticides, Herbicides, and Rodenticides
CONTRIBUTORS
Contributors

Peter M.C. DeBlieux, MD
Professor of Clinical Medicine, Louisiana State University Health Sciences Center; Professor of Clinical Surgery, Tulane University School of Medicine, New Orleans, Louisiana
Preface

Wyatt W. Decker, MD
Professor of Emergency Medicine, Mayo Clinic, Scottsdale, Arizona
Management of Emergencies Related to Implanted Cardiac Devices

Jorge del Castillo, MD, MBA
Clinical Associate Professor, Department of Emergency Medicine, University of Chicago, Pritzker School of Medicine, Chicago, Illinois
Associate Head, Division of Emergency Medicine, NorthShore University Healthsystem, Evanston, Illinois
Foot and Ankle Injuries

John Deledda, MD
Assistant Professor, Department of Emergency Medicine, Chief of Staff, University Hospital, University of Cincinnati, Cincinnati, Ohio
Cardiac Imaging and Stress Testing

Hand and Wrist Injuries

David H. Newman, MD
Director of Clinical Research, Associate Professor of Emergency Medicine, Department of Emergency Medicine, Mount Sinai School of Medicine, New York, New York
Evidence-Based Medicine
CONTRIBUTORS

Robert L. Rogers, MD
Associate Professor of Emergency Medicine and Medicine, Director, Medical Education and Teaching Fellowship, Department of Emergency Medicine, University of Maryland School of Medicine, Baltimore, Maryland Lung Transplant Complications

Carlo L. Rosen, MD
Program Director and Vice Chair for Education, Department of Emergency Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts Blunt Abdominal Trauma Penetrating Abdominal Trauma

Christopher Ross, MD, FACEP, FAAEM, FRCP
Assistant Professor, Rush Medical College; Associate Chair of Planning, Education and Research, Assistant Program Director, Department of Emergency Medicine, John H. Stroger Hospital of Cook County, Chicago, Illinois Peripheral Arterial Disease

Scott E. Rudkin, MD, MBA, RDMS, FAAEM, FACEP
Vice Chief, Department of Emergency Medicine, University of California, Irvine, Orange, California Demyelinating Disorders

Anne-Michelle Ruha, MD
Fellowship Director, Department of Medical Toxicology, Banner Good Samaritan Medical Center, Phoenix, Arizona Insecticides, Herbicides, and Rodenticides

Michael S. Runyon, MD
Director of Global Emergency Medicine, Assistant Program Director, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina Gastrointestinal Trauma

Annie T. Sadosty, MD
Assistant Professor, Department of Emergency Medicine, Mayo Clinic, Rochester, Minnesota Viral Infections

Tracy G. Sanson, MD
Education Director, Emergency Medicine Residency, Associate Professor, Department of Emergency Medicine, University of South Florida/Tampa General Hospital, Tampa, Florida Mesenteric Ischemia Diverticulitis

Jairo I. Santanilla, MD
Clinical Assistant Professor, Department of Medicine, Section of Emergency Medicine, Section of Pulmonary/Critical Care Medicine, Louisiana State University Health Sciences Center; Department of Pulmonary/Critical Care Medicine, Ochsner Medical Center, New Orleans, Louisiana Mechanical Ventilation

Sally A. Santen, MD, PhD
Assistant Dean, Educational Research and Quality Improvement; Associate Chair, Education, Department of Emergency Medicine, University of Michigan, Ann Arbor, Michigan Third Trimester Pregnancy Emergencies

Osman R. Sayan, MD
Assistant Director, Emergency Medicine Residency, NewYork-Presbyterian Hospital; Assistant Clinical Professor of Medicine, College of Physicians and Surgeons of Columbia University, New York, New York Endocarditis

Michael J. Schmidt, MD
Medical Director, Director of Emergency Department Informatics; Assistant Professor, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois Sepsis

Kathleen S. Schrank, MD
Professor of Medicine, Division Chief for Emergency Medicine, Department of Medicine, University of Miami Miller School of Medicine; Emergency Medical Services Medical Director, City of Miami Fire Rescue, Miami, Florida Constipation Joint Disorders

Jeremiah D. Schuur, MD, MHS
Director of Quality and Patient Safety, Director of Performance Improvement, Department of Emergency Medicine, Brigham and Women’s Hospital; Assistant Professor, Harvard Medical School, Boston, Massachusetts Quality and Patient Safety in Emergency Medicine

Theresa Schwab, MD, FRCP
Attending Physician, Department of Emergency Medicine, Advocate Christ Medical Center, Oak Lawn, Illinois; Assistant Professor, Department of Emergency Medicine, University of Illinois at Chicago College of Medicine, Chicago, Illinois Periarterial Disease

Wesley H. Self, MD, MPH
Assistant Professor, Department of Emergency Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee Hypoglycemia

Monique I. Sellas, MD
Attending Physician, Department of Emergency Medicine, Massachusetts General Hospital; Instructor, Department of Surgery, Division of Emergency Medicine, Harvard Medical School, Boston, Massachusetts Sexual Assault

Andrew W. Shannon, MD, MPH
Clinical Instructor, Department of Emergency Medicine, Louisiana State University Health Sciences Center, New Orleans, Louisiana Ultrasound-Guided Vascular Access

Ghazala Q. Sharieff, MD, MBA
Director of Pediatric Emergency Medicine, Palomar-Pomerado Health System/California Emergency Physicians; Clinical Professor, University of California, San Diego, San Diego, California Neonatal Cardiopulmonary Resuscitation Pediatric Resuscitation General Approach to the Pediatric Patient Pediatric Trauma

Rahul Sharma, MD, MBA, CPE, FACEP
Medical Director and Associate Chief of Service, Emergency Department, New York University Langone Medical Center—Tisch Hospital; Assistant Professor of Emergency Medicine, New York University School of Medicine, New York, New York Eye Emergencies

Philip Shayne, MD
Associate Professor, Department of Emergency Medicine, Emory University School of Medicine, Atlanta, Georgia Hypertensive Crisis

Ashley Shreves, MD
Assistant Professor, Departments of Emergency Medicine and Geriatrics and Palliative Medicine, Mount Sinai School of Medicine, New York, New York Evidence-Based Medicine

Amandeep Singh, MD
Physician, Department of Emergency Medicine, Alameda County Medical Center—Highland Hospital, Oakland, California Meningitis, Encephalitis, and Brain Abscess

Ellen M. Slaven, MD
Clinical Associate Professor of Medicine, Section of Emergency Medicine, Louisiana State University Health Sciences Center, New Orleans, Louisiana Human Immunodeficiency Virus Infection Skin and Soft Tissue Infections Antibiotic Recommendations

Mark Sochor, MD, FACEP
Associate Professor, Department of Emergency Medicine, University of Virginia, Charlottesville, Virginia Management of Cardiac Arrest and the Post-Cardiac Arrest Syndrome

Mitchell C. Sokolosky, MD
Associate Professor, Residency Program Director, Department of Emergency Medicine, Wake Forest University School of Medicine, Winston-Salem, North Carolina Pancreatic Disorders
Jeremy D. Sperling, MD  
Assistant Director, Emergency Medicine  
Residency Program, NewYork-Presbyterian Hospital; Assistant Professor of Clinical Medicine, Weill Cornell Medical College, New York, New York  
Introduction to Oncologic Emergencies

Sarah A. Stahmer, MD  
Associate Professor, Program Training Director, Department of Surgery, Division of Emergency Medicine, Duke University Hospital, Durham, North Carolina  
Bradyarrhythmias

Robert L. Stephen, MD  
Associate Professor, Division of Emergency Medicine, University of Utah Health Sciences Center, Salt Lake City, Utah  
Hypothermia and Frostbite

Matthew Strehlow, MD  
Clinical Associate Professor, Director, Clinical Decision Unit, Division of Emergency Medicine, Stanford University School of Medicine, Stanford, California  
Chest Pain

Mark Su, MD  
Assistant Professor of Emergency Medicine, Hofstra North Shore–UJI School of Medicine at Hofstra University; Fellow in Medical Toxicology, Department of Emergency Medicine, North Shore University Hospital, Manhasset, New York  
Hypoglycemic Agent Overdose

Amita Sudhir, MD  
Assistant Professor of Emergency Medicine, University of Virginia Health System, Charlottesville, Virginia  
Renal Failure

D. Matthew Sullivan, MD  
Associate Professor, Associate Director of Operations, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina  
Tuberculosis

Jeffrey Tabas, MD  
Associate Professor of Clinical Emergency Medicine, Department of Emergency Medicine, University of California, San Francisco, California  
Chest Pain

Taku Taira, MD  
Clinical Assistant Professor, Assistant Residency Director, Department of Medicine, Division of Emergency Medicine, Olive View–UCLA Medical Center, Sylmar, California  
Platelet Disorders

James K. Takayesu, MD,  
Associate Residency Director, Harvard-Affiliated Emergency Medicine Residency, Brigham and Women’s Hospital/Massachusetts General Hospital; Attending Physician, Department of Emergency Medicine, Massachusetts General Hospital, Boston, Massachusetts  
Documentation

Asim F. Tarabbar, MD  
Director, Medical Toxicology, Assistant Professor, Department of Emergency Medicine, Yale University School of Medicine; Quality Improvement Director, Emergency Department, Yale New Haven Hospital, New Haven, Connecticut  
Seizures

Danny G. Thomas, MD, MPH  
Assistant Professor of Pediatrics, Section of Emergency Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin  
Pediatric Traumatic Brain Injury

Kristine M. Thompson, MD  
Assistant Professor, Department of Emergency Medicine, Mayo Clinic, Jacksonville, Florida  
Viral Infections

Trevonne M. Thompson, MD  
Assistant Professor, Associate Director of Medical Toxicology, Department of Emergency Medicine, University of Illinois at Chicago College of Medicine, Chicago, Illinois  
Inhaled Toxins

Stephen Thornton, MD  
Toxicology Fellow, Division of Medical Toxicology, Clinical Instructor, Department of Emergency Medicine, University of California, San Diego, San Diego, California  
Marine Food-Borne Poisoning, Envenomation, and Traumatic Injuries  
Over-the-Counter Medications

T. Paul Tran, MD, MS, FACEP  
Associate Professor, Department of Emergency Medicine, University of Nebraska College of Medicine, Omaha, Nebraska  
Allergic Disorders

Jacob Ufberg, MD  
Associate Professor and Residency Director, Department of Emergency Medicine, Temple University School of Medicine, Philadelphia, Pennsylvania  
Cardiovascular and Neurologic Emergencies

Andrew S. Ulrich, MD  
Associate Professor, Executive Vice-Chair, Department of Emergency Medicine, Boston Medical Center, Boston University School of Medicine, Boston, Massachusetts  
Seizures

Michael C. Wadman, MD  
Associate Professor, Department of Emergency Medicine, University of Nebraska College of Medicine, Omaha, Nebraska  
Sodium and Water Balance

Ernest E. Wang, MD, FACEP  
Clinical Associate Professor, Assistant Dean for Medical Education, University of Chicago Pritzker School of Medicine; Medical Director, NorthShore Center for Simulation and Innovation, Division of Emergency Medicine, NorthShore University HealthSystem, Evanston, Illinois  
Cranial Nerve Disorders

N. Ewen Wang, MD  
Associate Professor, Division of Emergency Medicine, Stanford University School of Medicine, Stanford, California  
Pedicic Genitourinary and Renal Disorders

Danielle M. Ware-McGee, MD  
Clinical Instructor, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois  
Diseases of the Stomach

Abdominal Aortic Aneurysm

Ian S. Wedmore, MD, FACEP, FAWM, DiMM  
Program Director, Austere and Wilderness Medicine, Department of Emergency Medicine, Madigan Army Medical Center, Tacoma, Washington  
Chemical and Nuclear Agents

Natasha Wheaton, MD  
Resident Physician, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois  
Diseases of the Stomach

Beranton Whisenant, MD  
Assistant Professor and Director of Research, Department of Emergency Medicine, University of Florida College of Medicine—Jacksonville, Jacksonville, Florida  
Procedural Sedation

Max Wintermark, MD  
Associate Professor of Radiology, Neurology, Neurological Surgery, and Biomedical Engineering, Chief of Neuroradiology, Department of Radiology, University of Virginia, Charlottesville, Virginia  
Intracranial Hemorrhages
CONTRIBUTORS

Michael E. Winters, MD, FACEP, FAAEM
Associate Professor of Emergency Medicine and Medicine, University of Maryland School of Medicine; Co-Director, Combined EM/IM/Critical Care Program; Medical Director, Adult Emergency Department, University of Maryland Medical Center, Baltimore, Maryland

Stephen J. Wolf, MD
Senior Associate Program Director, Residency in Emergency Medicine, Department of Emergency Medicine, Denver Health Medical Center, Denver, Colorado; Associate Professor and Director of Medical Education, Department of Emergency Medicine, Assistant Dean for Advanced Studies, Office of Undergraduate Medical Education, University of Colorado School of Medicine, Aurora, Colorado

Richard E. Wolfe, MD
Chief of Emergency Medicine, Department of Emergency Medicine, Beth Israel Deaconess Medical Center; Associate Professor of Medicine, Department of Medicine, Harvard Medical School, Boston, Massachusetts

Todd Wylie, MD, MPH
Program Director, Pediatric Emergency Medicine Fellowship, Assistant Professor, Department of Emergency Medicine, University of Florida College of Medicine—Jacksonville, Jacksonville, Florida

Christine Yang-Kauh, MD
Assistant Program Director, Department of Emergency Medicine, New York Methodist Hospital, Brooklyn, New York

Timothy P. Young, MD
Assistant Professor of Pediatrics and Emergency Medicine, Department of Emergency Medicine, Loma Linda University Medical Center and Children’s Hospital, Loma Linda, California

Steven M. Zahn, MD
Assistant Medical Director, Department of Emergency Medicine, Sherman Hospital, Elgin, Illinois

Cristina M. Zeretzke, MD, FAAP
Section Chief, Pediatric Emergency Medicine, Our Lady of the Lake Regional Medical Center, Pediatric Residency Program, Baton Rouge, Louisiana

David K. Zich, MD
Assistant Professor of Medicine, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois

Amy E. Zosel, MD, MSCS
Assistant Professor, Department of Emergency Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Complications of Gynecologic Procedures, Abortion, and Assisted Reproductive Technology

Einthel and Venous Trauma and Great Vessel Injuries

Blunt Abdominal Trauma

Intracranial and Other Central Nervous System Lesions

Emergencies in Infants and Toddlers

Emergencies in the First Weeks of Life

Food- and Water-Borne Infections

### SECTION I

#### RESUSCITATION SKILLS AND TECHNIQUES

1. **Basic Airway Management** 1  
   David A. Caro

2. **Advanced Airway Techniques** 8  
   Aaron E. Bair and Erik G. Laurin

3. **Mechanical Ventilation** 19  
   Jairo I. Santanilla

4. **Shock** 28  
   Haney A. Mallemat and Michael E. Winters

5. **Emergency Cardiac Ultrasound: Evaluation for Pericardial Effusion and Cardiac Activity** 43  
   Michael P. Mallin and Christine Butts

6. **Ultrasound-Guided Vascular Access** 50  
   Andrew W. Shannon, Christine Butts, and Justin Cook

7. **Management of Cardiac Arrest and Post-Cardiac Arrest Syndrome** 55  
   William J. Brady, Peter P. Monteleone, Mark Sochor, and Robert E. O’Connor

8. **Trauma Resuscitation** 72  
   Trevor J. Mills

9. **Sonography for Trauma** 79  
   Christine Butts and Justin Cook

10. **Procedural Sedation** 85  
    Steven A. Godwin and Beranton Whisenant

11. **Resuscitation in Pregnancy** 92  
    Elizabeth M. Datner and Susan B. Promes

12. **Neonatal Cardiopulmonary Resuscitation** 97  
    Katherine Bakes and Ghazala Q. Shareef

13. **Pediatric Resuscitation** 103  
    Ghazala Q. Shareef and Katherine Bakes

14. **General Approach to the Pediatric Patient** 113  
    Ghazala Q. Shareef

15. **Emergencies in the First Weeks of Life** 117  
    John Nelson Perret and Cristina M. Zeretzke

16. **Emergencies in Infants and Toddlers** 129  
    Mark McIntosh and Todd Wylie

17. **Child with a Fever** 141  
    Jana L. Anderson, Christopher S. Kiefer, and James E. Colletti

18. **Approach to the Pediatric Patient with a Rash** 149  
    Anna K. McFarlin, Tracy Leigh LeGros, and Heather Murphy-Lavoie

19. **Pediatric Cardiac Disorders** 159  
    Nathan W. Mick

20. **Pediatric Genitourinary and Renal Disorders** 167  
    Suzanne Lippert and N. Ewen Wang

21. **Pediatric Gynecologic Disorders** 177  
    Jennifer F. Anders

22. **Pediatric Abdominal Disorders** 185  
    Russ Horowitz

23. **Pediatric Trauma** 190  
    Katherine Bakes and Ghazala Q. Shareef

24. **Pediatric Traumatic Brain Injury** 200  
    Danny G. Thomas

25. **Pediatric Orthopedic Emergencies** 204  
    Russ Horowitz

### SECTION II

#### HEAD AND NECK DISORDERS

26. **Eye Emergencies** 209  
    Kriti Bhatia and Rahul Sharma

27. **Ear Emergencies** 226  
    Thomas Morrissey and John B. Lissoway
CONTENTS

28. Dental Emergencies 236  
   Kip Benko
29. Pharynx and Throat Emergencies 249  
   H. Gene Hern, Jr.
30. Maxillofacial Disorders 259  
   Laura J. Bontempo

GASTROINTESTINAL DISEASES

31. Esophageal Disorders 269  
   Todd A. Guth
32. Diseases of the Stomach 279  
   Danielle M. Ware-McGee and Natasha Wheaton
33. Gastrointestinal Bleeding 286  
   Sheryl L. Heron and Patricia Baines
34. Mesenteric Ischemia 292  
   Kelly P. O’Keefe and Tracy G. Sanson
35. Diverticulitis 299  
   Kelly P. O’Keefe and Tracy G. Sanson
36. Inflammatory Bowel Disease 304  
   James Ahn
37. Constipation 309  
   Kathleen S. Schrank
38. Hernias 315  
   Chandra D. Aubin
39. Appendicitis 325  
   Rita A. Manfredi and Claudia Ranniger
40. Bowel Obstructions 331  
   Keith Boniface
41. Anorectal Disorders 336  
   John M. Boe
42. Liver Disorders 347  
   Richard Paula
43. Pancreatic Disorders 356  
   Mitchell C. Sokolosky
44. Biliary Tract Disorders 361  
   Julie J. Cooper
45. Emergency Biliary Ultrasonography 370  
   Bart S. Brown, Beatrice Hoffmann, and Vicki E. Noble
46. Gastrointestinal Devices, Procedures, and Imaging 382  
   Kerin A. Jones
47. Complications of Bariatric Surgery 390  
   Robert F. Poirier

THORACIC AND RESPIRATORY DISORDERS

48. Asthma 397  
   Rita K. Cydulka and Craig G. Bates
49. Chronic Obstructive Pulmonary Disease 405  
   Craig G. Bates and Rita K. Cydulka
50. Lung Infections 414  
   David S. Howes and Joseph F. Peabody
51. Pneumothorax 423  
   David E. Manthey and Bret A. Nicks
52. Pleural Effusion 431  
   Bret A. Nicks and David E. Manthey
53. Lung Transplant Complications 438  
   Michael K. Abraham and Robert L. Rogers

CARDIAC DISORDERS

54. Chest Pain 445  
   Matthew Strehlow and Jeffery Tabas
55. Acute Coronary Syndrome 452  
   David F.M. Brown
56. Cardiac Imaging and Stress Testing 469  
   Ryan T. Geers, John Deledda, and Andra L. Blomkalns
57. Congestive Heart Failure 476  
   Joshua M. Kosowsky
58. Bradyarrhythmias 487  
   Sarah A. Stahmer
59. Tachydysrhythmias 497  
   Keith A. Marill
60. Pericarditis, Pericardial Tamponade, and Myocarditis 514  
   Amal Mattu and Joseph P. Martinez
## CONTENTS

### Cardiac Valvular Disorders 524
Pierre Borczuk

### Endocarditis 530
Osman R. Sayan and Wallace A. Carter

### Management of Emergencies Related to Implanted Cardiac Devices 547
Daniel Cabrera and Wyatt W. Decker

### Syncope 557
James Quinn

CONTENTS

96. Vertigo 830
   Andrew K. Chang

97. Peripheral Nerve Disorders 839
   Phillip Andrus and Swathi Nadindla

98. Demyelinating Disorders 850
   Scott E. Rudkin

99. Seizures 857
   Asim F. Tarabar, Andrew S. Ulrich, and Gail D’Onofrio

100. Transient Ischemic Attack and Acute Ischemic Stroke 870
    Holly K. Ledyard

101. Headache 881
    Joshua N. Goldstein and Jonathan A. Edlow

102. Intracranial and Other Central Nervous System Lesions 890
    Steven M. Zahn

103. Intracranial Hemorrhages 896
    J. Stephen Huff, Max Wintermark, and Chris A. Ghaemmaghami

104. Delirium and Dementia 905
    Andy Jagoda and Haru Okuda

105. Neurologic Procedures 912
    Brian A. Stettler and Edward C. Jauch

IMMUNE SYSTEM DISORDERS

106. Allergic Disorders 917
    Aaron N. Barksdale and T. Paul Tran

107. Joint Disorders 929
    Kathleen S. Schrank

108. Systemic Lupus Erythematosus 944
    James G. Adams

109. Connective Tissue and Inflammatory Disorders 949
    Raveendra S. Morchi

110. Vasculitis Syndromes 959
    Paul J. Allegretti and Keri Robertson

GENITOURINARY AND RENAL DISEASES

111. Male Genitourinary Emergencies 969
    Jonathan E. Davis

112. Nephrolithiasis 976
    Carl R. Menckhoff

113. Hematuria 984
    M. Kit Delgado and Eva M. Delgado

114. Renal Failure 990
    William J. Brady and Amita Sudhir

115. Emergency Renal Ultrasonography 998
    Mark W. Byrne, Heidi H. Kimberly, and Vicki E. Noble

116. Dialysis-Related Emergencies 1003
    Yi-Mei Chng and Gregory H. Gilbert

117. Renal Transplant Complications 1011
    Gerald Maloney

SECTION XII

WOMEN’S HEALTH AND GYNECOLOGIC DISEASES

118. The Healthy Pregnancy 1015
    Jacqueline Khorasanee and Matthew Kippenhan

119. Disorders of Early Pregnancy 1023
    Matthew Kippenhan

120. First Trimester Ultrasonography 1034
    Cindy W. Chan, Michael Lambert, and Vicki E. Noble

121. Third Trimester Pregnancy Emergencies 1041
    Sally A. Santen and Robin R. Hemphill

122. Emergency Delivery and Peripartum Emergencies 1051
    Jeremy B. Branzetti

123. Postpartum Emergencies 1061
    Fiona E. Gallahue

124. Gynecologic Pain and Vaginal Bleeding 1069
    Jamie L. Collings and Nicholas A. Borm

125. Complications of Gynecologic Procedures, Abortion, and Assisted Reproductive Technology 1079
    Christine Yang-Kauh

126. Gynecologic Infections 1097
    Jamil D. Bayram and Mamta Malik

127. Breast Disorders 1114
    Robert Lockwood and Jamie L. Collings
## ENVIRONMENTAL DISORDERS

130. **Heat-Related Emergencies** 1135  
   Virgil Davis

131. **Hypothermia and Frostbite** 1142  
   Robert L. Stephen

132. **Lightning and Electrical Injuries** 1148  
   Christopher B. Colwell

133. **Dysbarism, Dive Injuries, and Decompression Illness** 1153  
   Heather Murphy-Lavoie and Tracy Leigh LeGros

134. **Submersion Injuries** 1162  
   Mohammed A. Abu Aish and Niranjan Kissoon

135. **Acute Radiation Emergencies** 1167  
   Bradley A. Dreifuss

136. **Smoke Inhalation** 1178  
   Thomas Kunisaki and Steven A. Godwin

137. **Chemical and Nuclear Agents** 1182  
   Christopher S. Kang and Ian S. Wedmore

## BITES, STINGS, AND INJURIES FROM ANIMALS

138. **Mammalian Bites** 1187  
   Ashley Booth Norse

139. **Venomous Snakebites in North America** 1192  
   Robert L. Norris

140. **Arthropod Bites and Stings** 1203  
   Joshua N. Nogar and Richard F. Clark

141. **Non-Snake Reptile Bites** 1211  
   Stephen C. Hartsell and Troy E. Madsen

142. **Marine Food-Borne Poisoning, Envenomation, and Traumatic Injuries** 1216  
   Stephen Thornton and Richard F. Clark

## TOXICOLOGIC EMERGENCIES

143. **General Approach to the Poisoned Patient** 1221  
   Amy E. Zosel

144. **Acetaminophen, Aspirin, and NSAIDs** 1231  
   Heather Long

145. **Anticholinergics** 1239  
   Jessica A. Fulton and Lewis S. Nelson

146. **Insecticides, Herbicides, and Rodenticides** 1246  
   Robert D. Cannon and Anne-Michelle Ruha

147. **Antidepressants and Antipsychotics** 1257  
   Michael R. Christian and Sean M. Bryant

148. **Cardiovascular Drugs** 1266  
   Kirk L. Cumpston

149. **Sympathomimetics** 1280  
   Mae F. De La Calzada-Jeanlouie and Gar Ming Chan

150. **Hallucinogens and Drugs of Abuse** 1286  
   Mark B. Mycyk

151. **Toxic Alcohols** 1292  
   Mark B. Mycyk

152. **Hydrocarbons** 1299  
   David D. Gummin

153. **Inhaled Toxins** 1308  
   Trevon M. Thompson

154. **Ethanol and Opioid Intoxication and Withdrawal** 1314  
   Patrick M. Lank and Shana Kusin

155. **Sedative-Hypnotic Agents** 1323  
   James W. Rhee and Timothy P. Young

156. **Hypoglycemic Agent Overdose** 1329  
   Mark Su

157. **Over-the-Counter Medications** 1334  
   Stephen Thornton and Binh T. Ly

158. **Pediatric Overdoses** 1343  
   Shana Kusin and Patrick M. Lank

## METABOLIC AND ENDOCRINE DISORDERS

159. **Fluid Management** 1351

Rapid-sequence intubation (RSI) is the technique of combining sedation and paralysis to create optimal intubating conditions to facilitate emergency intubation. RSI has become the standard in emergency airway management, with intubation success rates greater than 99%. The emergency airway operator should fully understand the risks and benefits and also know when to deviate from its standard algorithm.

Initial assessment of the patient’s airway may identify key features that will help guide airway management. This assessment may have to proceed simultaneously with supportive airway maneuvers.

Anatomically, one should assess the patient by looking for facial distortion and the position in which the airway is held. Drooling or inability to tolerate secretions may be apparent and are ominous signs that suggests significant supraglottic irritation. Patients should be asked to open their mouth, or if they are obtunded, a jaw-thrust and mouth-opening maneuver should be performed carefully to determine how far it can be opened. Palpation of facial structures includes determination of nasal, maxillary, and mandibular stability. Maxillary instability, in particular, should alert the practitioner to be cautious with any nasal intubation, whether by nasal trumpet, nasogastric tube, or blind nasotracheal intubation, because intracranial misplacement of nasal trumpets and nasogastric and nasotracheal tubes has been reported. Once past the facial structures, the tongue should be viewed. Similarly, the hard and soft palate, as well as the tonsils, should be evaluated.

Functional assessment is performed to determine whether the patient can move air and phonate. Specific airway noises should be noted, especially stridor. Such assessment leads the clinician to evaluate for specific indications for intubation (Box 1.1). Oxygenation failure can be defined as an inability to maintain oxygen saturation greater than 90% despite optimal oxygen supplementation (the exception is a patient with chronic obstructive pulmonary failure, who typically maintains a saturation of 85% to 90%). Ventilatory failure is usually measured by clinical features, including respiratory rate, abnormal depth or work of breathing, abnormal breathing patterns, accessory muscle use, inability to speak in complete sentences, presence of abnormal airway sounds (stridor or severe wheezing), or altered mental status. Studies also point to end-tidal carbon dioxide measurement as an aid in procedural sedation, but it is potentially unable to accurately predict PaCO₂ in patients with dyspnea.

Acute obtundation diminishes a patient’s ability to sense irritant stimuli and therefore spontaneously protect the airway. This is part of the rationale for using a Glasgow Coma Scale score of 8 or lower as a cue to intubate trauma patients. Traditionally, the gag reflex has been used to determine whether a patient’s airway reflexes are intact. Stimulation of a gag reflex in an obtunded or trauma patient may result in unwanted patient reactions, however, such as bucking, gagging, coughing, or actual vomiting; additionally, up to 37% of healthy volunteers fail to demonstrate a gag reflex. Alternatively, a patient who swallows spontaneously while recumbent has sensory and motor paths capable of protecting the airway. In addition, recent articles have questioned use of the Glasgow Coma Scale score in nontrauma patients and instead emphasize clinical judgment in making the decision to intubate.

### Section I: Resuscitation Skills and Techniques

#### Basic Airway Management

David A. Caro

KEY POINTS

- Establishment of a patent airway is the cornerstone of successful resuscitation and a defining proficiency of emergency medicine.
- Basic airway management includes the initial airway evaluation and identification and use of interventions to maintain oxygenation and ventilation. These interventions might be simple, such as the application of supplemental oxygen, or complex, such as noninvasive ventilation or emergency tracheal intubation.
- The goal of emergency intubation is safe, successful intubation of the trachea with an endotracheal tube that allows oxygenation and ventilation while protecting the airway from aspiration.
- Patients in the emergency department are always considered high risk because they have not been evaluated beforehand, may have eaten recently, may have anatomic obstacles that are not readily apparent, or may have unstable hemodynamic parameters.

Finally, the patient’s anticipated course will serve as an intubation criterion if loss of airway patency or protection is predicted within the near future.

**CRITICAL AIRWAY PHYSIOLOGY**

**OXYGENATION TECHNIQUES**

The binding of oxygen to hemoglobin is not linear. Hemoglobin tends to bind oxygen well until the partial pressure of oxygen decreases to 60 mm Hg, and then it rapidly dissociates to allow diffusion of oxygen into blood and surrounding tissue. An oxygen partial pressure of 60 mm Hg correlates with an oxygen saturation of approximately 90% (Fig. 1.1). This is an important correlation that should be kept in mind throughout resuscitation (Table 1.1).

Patients who require intubation should be preoxygenated with a nonrebreather mask. The goal is to wash as much nitrogen out of the lungs as possible and replace it with oxygen.19-21

When the patient is paralyzed during RSI, this reservoir will permit continued delivery of oxygen to the alveoli for some time, thereby allowing the patient to maintain oxygen saturation while apneic. Five or more minutes of preoxygenation allows this reservoir to develop. Alternatively, if pressed for time, the patient can be asked to take eight vital capacity breaths through the nonrebreather in an attempt to build as great a reservoir as possible.22 Not surprisingly, critically ill patients have decreased oxygen reserve and tolerate apnea less well than do relatively healthy subjects.19,20-22

Positive pressure will occasionally be required to oxygenate a patient before intubation. A critical feature of RSI is avoidance of active bag-mask ventilation unless it is absolutely necessary.23 Active bag-mask ventilation with oxygenation is reserved for patients whose oxygen saturation is below 90%.8 Any positive pressure ventilation will not only ventilate the lungs but also insufflate the stomach. This fact is critical to

**Fig. 1.1 Oxygen-hemoglobin dissociation curve.** Four different ordinates are shown as a function of oxygen partial pressure (the abscissa). In order from right to left, they are saturation (%), O₂ content (mL of O₂/0.1 L of blood), O₂ supply to peripheral tissues (mL/min), and O₂ available to peripheral tissues (mL/min), which is calculated as O₂ supply minus the approximately 200 mL/min that cannot be extracted below a partial pressure of 20 mm Hg. Three points are shown on the curve: a, normal arterial pressure; f, normal mixed venous pressure; and P₅₀, the partial pressure (27 mm Hg) at which hemoglobin is 50% saturated. (From Miller RD, editor. Miller’s anesthesia. 6th ed. Philadelphia: Churchill Livingstone, 2005.)
the performance of RSI because a paralyzed patient is at risk for aspiration as a result of relaxed esophageal sphincter tone, especially if the stomach is distended with air. Active bag ventilation and oxygenation may need to be performed in patients who are experiencing acute oxygenation failure. Most adult bag-mask devices have reservoirs greater than 1 L and can deliver high-flow oxygen if a good mask seal is maintained. Alternatively, continuous positive airway pressure or bilevel positive airway pressure can provide a constant level of positive pressure support or two levels of pressure support, respectively, through a tightly fitted mask that fits over the nose or the mouth and nose, if applied in a timely manner in the correct patient, the need for intubation might be averted.

**Bag-Mask Technique**

Bag-mask oxygenation plus ventilation is a critical skill that all airway managers must master before learning to perform RSI (Boxes 1.2 and 1.3). Application of the bag and mask requires proper patient positioning and correct application of a mask seal. The ideal position for mask ventilation is with the patient supine and the head and neck in the sniffing position. A proper mask seal is obtained by opposing the mask to the facial skin to create a good air seal. Additionally, new extraglottic devices are available that allow bag ventilation with an inflated balloon surrounding the glottis. These devices can also be used to ventilate and oxygenate patients who do not have contraindications (Box 1.4).7,30-37

**EMERGENCY AIRWAY ALGORITHM**

A patient who merits intubation and is dead or nearly so (a crash airway) requires immediate orotracheal intubation or a timely manner in the correct patient, the need for intubation might be averted.

**BOX 1.2 Failed Airway Fallback**

Mask ventilation is the initial airway management modality of choice for any patient who fails to maintain adequate oxygenation with a nonrebreather mask or begins to desaturate below 90% while apneic during an attempt at rapid-sequence intubation.8

**BOX 1.3 Requirements for Adequate Bag-Mask Oxygenation and Ventilation Technique**

Proper positioning
- Sniffing position if possible
- Airway adjuncts such as nasal trumpets or oral airways in appropriate patients

Proper mask seal
- Two-person technique, with one solely responsible for the mask seal, is best
- Jaw-thrust maneuver: pull the mandible up to the mask

**BOX 1.4 Causes of Airway Difficulty**

Problems with bag ventilation: MOANS (Mask seal, Obesity, Age >50 years old, Neck mobility, Snoring)7,30
Problems with laryngoscopy: LEMON (Look for airway distortion, Evaluate mouth opening and thyromental distance, Mallampati score, Obstruction, Neck mobility)31-37
Problems with cricothyrotomy: SHORT (previous neck surgery, expanding neck hematoma, Obesity, previous radiation therapy, and Tumors and abscesses that might distort the anatomy)
Problems with the use of extraglottic devices: RODS (Restricted mouth opening, Obstruction, Disrupted or distorted airway, Stiff lungs or cervical spine)36

Orotracheal intubation is now the preferred method of emergency intubation, either by direct laryngoscopy or by video laryngoscopy.42-46 The process of intubation includes proper patient positioning, clinician positioning, tool choice and assembly, and technique of laryngoscopy. In performing standard oral intubation, the patient lies flat and supine while positioning of the patient’s head is addressed.43 Patients with immobile cervical spines, whether secondary to trauma, arthritis, or other causes, should not have their heads or necks manipulated, and the head should be maintained in a neutral position with in-line stabilization by a person designated for this task.45,46 If mobility is not an issue, the age of the patient and size of the occiput determine the need for elevation of the patient’s shoulders or head. Infants have a relatively large occiput with respect to their bodies and will therefore passively flex their head forward when lying flat.47 This makes a more acute angle that the laryngoscopist has to navigate. The airway axes will align better if the infant’s shoulders are elevated. An adult’s head is relatively smaller and tends to extend at the cervicothoracic junction instead of flexing. This counterintuitively moves the laryngeal and pharyngeal axes into an alignment that is less parallel and can be overcome by placing a roll under the adult’s head.47 A key anatomic relationship to keep in mind is that the head is ideally aligned when an imaginary line drawn between the tragus of the ear and the anterior axillary line is parallel to the floor.

Standard orotracheal intubation is performed with the practitioner at the head of the bed looking down at the patient’s face. The clinician gently grasps the laryngoscope with the fingertips of the left hand. Using the right hand, the clinician opens the patient’s mouth in either a scissoring technique with the thumb and index finger or by grasping the mentum and moving it caudally to expose the mouth. The blade of the laryngoscope is then gently inserted into the right side of the mouth and advanced into the pharynx.

The direct laryngoscope blades most commonly used for emergency intubation are the curved Macintosh blade and the straight Miller blade. Traditional intubation with the Macintosh blade begins with insertion of the blade at the right corner of the mouth. The blade is advanced under direct visualization, is swept to the midline, and concomitantly sweeps the tongue to the patient’s left. The tip of the blade is directed into the vallecula, and the laryngoscope is then pushed up as a unit. The epiglottis is lifted up because of its connection to the hyoepiglottic ligament, which attaches to the posterior surface of the mucosa behind the hyoid and the base of the epiglottis. Lifting of the epiglottis exposes the vocal cords and glottis.

Traditional intubation with the Miller blade is similarly performed by inserting the blade in the right side of the mouth and maintaining the position of the blade on the right side of the tongue while the blade is inserted to the epiglottis, again under direct visualization. Tongue control is a major issue, with the blade pushing the tongue upward and to the left. The laryngoscope is then pushed upward to physically lift the epiglottis and expose the vocal cords.

Video laryngoscopic intubation is the newest method of orotracheal intubation and has developed into a valid option for primary intubation in the majority of patients. Multiple options exist, and each has its own method of how it is used.48 The benefit of these devices is that they routinely provide a laryngoscopic view superior to that possible with direct laryngoscopy in the vast majority of patients in whom they are used.42,43,49,50 The angles required for passage of the tube may sometimes present the key challenge, so this is an additional focal point of training. As with any video-based system, the principal downside is the potential for obstruction of the operator’s view if blood, vomitus, or excessive secretions are present in the oropharynx.

Finally, nasotracheal intubation is another option for intubation, although its use is decreasing in favor of directly
visualized oral intubation. Nasotracheal intubation requires a breathing patient because the patient’s breath sounds will guide the intubator in placing the tube. Nasotracheal intubation should not be considered a primary mode of intubation because its success rate has clearly been shown to be lower than that of orotracheal intubation with RSI.51

**MEDICATIONS, PHARMACOLOGY, AND PHYSIOLOGIC RESPONSES TO MEDICATION CLASSES**

**SEDATIVE AGENTS**
Multiple sedatives can be used for RSI. Use of a sedative humanely allows amnesia and sedation, thereby potentially improving laryngoscopy and intubation.51 The choice of sedative agent for a given clinical scenario differs according to the pathophysiologic parameters that the clinician observes or anticipates to occur during the attempt at RSI. Hemodynamic instability, elevated intracranial pressure, and bronchospasm are some of the most common complicating factors that the clinician must consider during preparation for sedation. A list of sedative agents used for RSI and their side effect profiles can be found in Table 1.2.

The most commonly used sedatives in current emergency practice include midazolam (Versed) and etomidate (Amidate). Doses of midazolam recommended in the anesthesia literature are 0.1 to 0.3 mg/kg intravenously. The danger of using midazolam in these doses is the hypotension that it generates, especially in critically ill patients. Most practitioners will intentionally underdose midazolam in the setting of RSI for this specific reason.52

Etomidate is administered at a dose of 0.3 mg/kg intravenously and does not cause the hypotension seen with midazolam.52-64 Etomidate does cause reversible cortisol suppression, however, and is no longer used as a drip for long-term sedation. The effect on cortisol after a single dose has been demonstrated to resolve spontaneously and has not been shown to have an effect on patient outcome.55 Controversy has recently developed regarding the use of etomidate in patients with sepsis. One major study reportedly identified etomidate as a causal agent in increasing mortality in this patient population.56,57 However, this study was underpowered and not designed to look for this concern, and its findings were based on post hoc analysis of the study results.58 At least one small-scale study has demonstrated no increase in mortality between etomidate and midazolam in this setting.59 No large-scale study exists at the time of this writing to specifically answer this question, but with the overwhelming success of single-dose etomidate in emergency intubations, definitive studies would be necessary to change practice.

**NEUROMUSCULAR BLOCKING AGENTS (PARALYTICS)**
The paralytics commonly used for RSI include depolarizing agents (succinylcholine) and nondepolarizing agents (vecuronium, rocuronium). Succinylcholine has been studied extensively and is the classic agent used for RSI. It has a short time of onset (approximately 45 seconds), a short duration of action (approximately 5 to 10 minutes), and a wide dosing margin (the typical dose for RSI is 1.5 mg/kg, but doses up to 6 mg/kg do not change its pharmacokinetics).60 Succinylcholine also has some significant side effects, including occasionally significant hyperkalemia, fasciculations, and malignant hyperthermia. Any airway manager who plans to use succinylcholine should be well versed in its mechanism of action, as well as its potentially significant and life-threatening side effects (Box 1.5).

Rocuronium has recently come into favor as a nondepolarizing agent that can provide succinylcholine-like intubating conditions in 45 to 60 seconds, provided that the correct dose (1.0 to 1.2 mg/kg intravenously) is used.61-63 The benefits of using a nondepolarizing agent include the absence of fasciculations and hyperkalemia. The duration of action of nondepolarizing agents is much longer than that of succinylcholine, however, with rocuronium being the shortest acting at 45 to 60 minutes. See Table 1.3 for a list of commonly used nondepolarizing paralytic agents.

**PRETREATMENT AGENTS**
Some medications have the potential to aid in promoting physiologic responses to intubation if given as pretreatment agents. The typical laryngoscopy in an adult will result in sympathetic stimulation that could be detrimental in certain

parasympathetic stimulation and resultant bradycardia, which has led some experts to advocate a pretreatment dose of atropine before attempts at pediatric intubation. Current recommendations are to use atropine for all intubations in children younger than 1 year and to have the drug available for those older than 1 year.57

**PUTTING IT TOGETHER: RAPID-SEQUENCE INTUBATION**

RSI is the technique of combining sedation and paralysis to create the most optimal intubating conditions during emergency intubation (Box 1.6).1,9,22,47,75 Seven checklist points have been identified to help clinicians prepare for emergency RSI (Box 1.7).22 Also known as the 7 P’s, this or a similar checklist can be used during each intubation in which airway managers participate.22 This tool should be viewed as a patient safety device and an error minimization instrument. As with any high-stakes activity, the use of memory aids and algorithms can reduce the cognitive load associated with decision making and allow the practitioner to focus on the specific task at hand.76

Protection of the airway refers to the use of cricoid ring pressure (Sellick maneuver) during the process of paralysis, intubation, and confirmation of endotracheal placement. The cricoid ring is compressed with an assistant’s index finger and thumb in an attempt to compress the underlying esophagus and prevent passive regurgitation of stomach contents into the trachea.75,76 The amount of force recommended is equivalent to the amount required to create discomfort when pressing with the same fingers on the bridge of the nose.18 Some studies have identified improper Sellick maneuver technique as a potential obstruction to laryngoscopy and placement of the endotracheal tube (ETT), but it might help prevent gastric
insufflation during attempts at bag-mask ventilation and is currently recommended if resources permit.\textsuperscript{19}

The sixth step is passage of the tube. Laryngoscopy is performed at approximately 1 minute after the paralytic agent has been administered. The ETT is placed under direct vision (either line of sight or with video monitoring) through the cords and into the trachea. An adult man should typically have the tube placed orally to a depth of 24 cm, and an adult woman should typically have the tube inserted to 21 cm. A general rule of thumb is that the ETT should be inserted to three times its size.\textsuperscript{79} Placement of the ETT is considered complete once objective verification of placement has occurred, typically by end-tidal carbon dioxide detection.\textsuperscript{80,81}

**SUMMARY**

Emergency airway management involves a combination of techniques and strategies designed to ensure success of intubation in critically ill patients. The approach to an emergency airway is necessarily different from that taken for an elective or urgent case. The airway manager must have a solid foundation in ventilation techniques (bag-mask, extraglottic devices), which will be the first rescue device. Assessment of the airway is a critical skill that mandates a methodic approach to ensure that a difficult airway is recognized and appropriately planned for. The use of RSI has revolutionized emergency intubation, and a set of strategies is required to deal with routine intubations and difficult airways. Management of difficult airways is discussed in Chapter 2.

SECTION I  RESUSCITATION SKILLS AND TECHNIQUES

anticipated and unanticipated difficult airways more likely, with some estimates as high as 20%. Fortunately, however, the frequency of intubation failure in the ED is much lower and approximates 1%. The prevalence of airways requiring rescue from previous failed attempts in the ED is difficult to determine. What is apparent is that rescue devices are not used routinely, although they are commonly available.

**ANTICIPATED DIFFICULTY**

Multiple predictors related to airway anatomy have been reported in the anesthesia literature, but none have been shown to be useful in isolation for predicting intubation difficulty. However, some evidence suggests the use of a limited set of assessments in patients undergoing airway management in the ED. The LEMON mnemonic has been proposed for this purpose (Box 2.1) (see Chapter 1). If difficulty is predictable and the patient is not a suitable candidate for RSI, the optimal approach depends on the previous training of the intubator and the availability of advanced airway tools.

**UNANTICIPATED DIFFICULTY**

Every patient in any environment has the potential for unexpectedly being difficult to intubate. Unexpectedly encountering blood, emesis, a mass, an anatomic variant, or evolving traumatic injury can all result in a challenging airway. In this chapter we attempt to organize and briefly define some of the many rescue techniques that might be used in emergency practice.

**ANTICIPATED DIFFICULT AIRWAY**

Only a small fraction of patients undergoing ED intubation are actually deemed poor candidates for RSI, even though many patients are expected to be difficult to intubate. No discreet threshold at which RSI is deemed to be safe and when it is contraindicated has ever been determined, partly because of the lack of sensitivity of the various difficult airway prediction tools. Importantly, many ED patients are in extremis and unable to cooperate with a preprocedural examination. Much of what is discussed in the current literature is based on the anesthesia experience, which generally reflects the "elective" intubation of cooperative patients. Nevertheless, it is often useful to perform a preprocedural assessment, as allowed by time constraints and the patient’s condition. Some
Difficult airway algorithm.

requires that the intubator actively move the larynx to

pression). The process of laryngeal manipulation is active. It

is predicated on the answers to several key questions:

- Is there enough time to plan a methodic approach?
- Despite the identified presence of difficult airway predic-
tors, can RSI still be used safely?
- Is the patient’s oxygenation adequate?

Understanding these issues in context to a given clinical sce-
nario will help in the decision-making process regarding alter-
native approaches.

RAPID-SEQUENCE INTUBATION FOR A DIFFICULT AIRWAY

RSI is preferred for the vast majority of intubations performed
in the ED. It is important to realize that provider familiarity
will probably be the major determinant regarding device and

technique selection beyond the use of RSI. For this reason it

is prudent to focus on techniques that are likely to remain
familiar through frequent use. Accordingly, the use of opti-

mized and augmented laryngoscopy merits discussion because
these concepts are simply extensions of “routine” RSI.

OPTIMIZED LARYNGOSCOPY

Routine direct laryngoscopy relies on manipulation of the soft

structures of the hypopharynx and the base of the tongue into the

relatively fixed proportions of the mandible. The goal of such

manipulation is to allow a direct line of sight to the larynx

and vocal cords. This, however, can be difficult given certain

unalterable variables of patient anatomy. The process of opti-
mizing the view is probably the simplest and often the least

appreciated of the skills of an expert airway manager. The

features of optimization are discussed in the following
sections.

Head and Neck Positioning

In the absence of cervical spine immobilization, active range

of neck flexion and extension can frequently provide markedly

improved visualization.23

External Laryngeal Manipulation

External manipulation of the larynx is distinct from the famil-

iar cricoid pressure concept (e.g., the Sellick maneuver). It is,

however, related to BURP (backward, upward, rightward

pressure). The process of laryngeal manipulation is active. It

requires that the intubator actively move the larynx to

maximize visualization of the laryngeal structures. Generally,

once the view is optimized, an assistant will be required to

maintain the preferred positioning.24-26

Facility with Various Blade Types

Laryngoscope blade types come in various sizes and shapes

and therefore have various advantages and disadvantages. In

general, two formats are used with regularity: curved (e.g.,

Macintosh) and straight (e.g., Miller). Curved blades are often

best for sweeping the tongue laterally. Some patients may be
difficult to intubate because of an elongated or anteriorly

oriented vallecula and epiglottis. In such cases, a straight

blade may prove to be useful. Although most practitioners

will have a preferred blade, it is important to maintain facility with

both general blade types because they often have offsetting

advantages. Additionally, a multitude of variably profiled

laryngoscopes with adjunctive prisms and mirrors are avail-

able. These devices are not frequently used in emergency

practice.

AUGMENTED LARYNGOSCOPY

This concept refers to using an assistive device to either
extend the view of the intubator (i.e., fiberoptic stylet) or assist
in tube placement with use of a narrow-diameter introducer.

Such introducers have been used for decades and come in
various formats (i.e., Eschmann, Frova). The leading tip of
these introducers is angled anteriorly to provide tactile feed-
back regarding location of the introducer. These devices can
be valuable when visualization is limited.
ALTERNATIVE TECHNIQUES FOR THE ANTICIPATED DIFFICULT AIRWAY

**Fiberoptics**

As a class, directable and flexible scopes have been available for decades. They have recently been made more portable by replacing the heavy light source with a battery pack. These devices are consequently more convenient in the hurried ED. The majority of the products currently on the market consist of a directable cable mechanism associated with a light source and fiberoptic bundle. Notable issues are that the glass fibers that constitute the optics are breakable and small amounts of debris can greatly diminish viewing quality. Historically, these devices were considered too expensive or impractical. In the future, however, these type of flexible and directable devices will probably become more available. To date, relatively little research relevant to emergency medicine practice has been conducted.2,27-29 A recent query of emergency medicine training programs in the United States suggests that the majority maintain this type of equipment,11 but clinical expertise is variable.

**FLEXIBLE AND DIRECTABLE FIBEROPTICS** Flexible and directable fiberoptic models are portable and have variable diameters and lengths. This equipment varies depending on its intended purpose. The shorter nasopharyngoscope is approximately 35 cm in length, in contrast to the 60-cm bronchoscope. The goal is to directly visualize the glottis via the nares or mouth. Once the cords are visualized, the tip of the fiberoptic scope is advanced into the airway to the level of the carina. The preloaded endotracheal tube is then advanced over the scope and into the airway. Efficacy of this technique in an awake patient requires adequate patient and equipment preparation (Box 2.2).

**FLEXIBLE AND NONDIRECTABLE FIBEROPTICS** Flexible and nondirectable fiberoptics have been designed to be used from within the lumen of an endotracheal tube. They all share in common the issues related to obstruction of view with debris. Additionally, any attempt to direct the tip of the device relies on manipulation of the associated endotracheal tube with visual feedback through either an eyepiece or video monitor. Despite these shortcomings, these devices are attractive because the nondirectable group is generally regarded as more durable and tends to be less expensive. An example of this type of device is the Trach View (Parker Medical, Englewood, CO).

**SEMI-RIGID FIBEROPTICS** The semirigid fiberoptic scope is, conceptually, a semimalleable stylet with internal fiberoptic bundles.34 These devices are similar to the nondirectable class

---

**TIPS AND TRICKS**

Even though a complete tutorial of the technical details of using flexible fiberoptics is beyond the scope of this review, several technique pearls are worth highlighting:

1. Recognize that the procedure will take at least 15 to 20 minutes to accomplish. If the patient cannot tolerate such a wait, use of this technique may be misguided.
2. Stay in the anatomic midline at all times during the procedure. Straying laterally will often result in poor visualization and inability to pass the vocal cords.
3. Keep the slack out of the scope. If slack is present along the length of the scope, rotation of the body of the scope will not translate into rotation of the tip.
4. The size of the working channel in many scopes is often too small for suction to be effective.
5. If the tube is resistant to passage of the scope into the airway, it is likely that the tip of the tube, or Murphy’s eye, is caught at the level of the arytenoids. Rotation of the entire tube-scope apparatus 45 to 90 degrees will probably overcome the obstruction.
6. Further considerations:
   - Nasal approach. This route may be better tolerated by the patient and will not subject the equipment to damage from biting by the patient. However, it is prone to cause bleeding with passage of the tube. Adequate vasoconstriction is key. Partially intubating the chosen naris with the endotracheal tube can often simplify the procedure by avoiding the obscuring materials in the nasopharynx. Beware, however, that placing the tip of the tube too deep into the posterior pharynx will make subsequent scope manipulation challenging because of the acute angle that will be required for the tip of the scope to reach the glottis. Optimally, the tip of the endotracheal tube should be placed at the level of the uvula before attempting to advance the scope to the vocal cords.
   - Oral approach. This may be advantageous if a larger endotracheal tube is needed. However, a bite block or a device that provides an oropharyngeal conduit may be necessary if there is a possibility of the patient biting the equipment. Additionally, a fiberoptic technique can be used in conjunction with a second provider using a laryngoscope to manipulate the soft tissues of the oropharynx.
   - Adjunctive use. Use of flexible fiberoptics through a laryngeal mask airway or similar device has been described.35-33

---

**BOX 2.2 Patient Preparation**

If using a nasal approach, adequate topical anesthesia and vasoconstriction can be achieved with various agents via an atomizer.

If using an oral approach, various spray anesthetic agents can be used in addition to a nebulized agents (e.g., lidocaine). Additionally, gargled lidocaine (4%) can be effective, patient cooperation permitting.

An antisialagogue (e.g., glycopyrrolate) can be useful to allow better tissue absorption of topical anesthetic agents. However, at least 20 minutes is needed for efficacy as a drying agent.

Sedation is used, as necessary, to achieve reasonable anxiolysis to improve patient cooperation.

Preoxygenation, as always, is fundamental to procedural sedation and airway management.
of fiberotics with respect to image quality and durability. An example of this type of device is the Shikani optical stylet (Clarus Medical, LLC, Minneapolis, MN).

**Rigid Fiberotics** Rigid fiberoptic scopes consist of an imaging bundle enclosed within a rigid L- or J-shaped assembly. This shape is designed for placement into the hypopharynx with subsequent indirect visualization of the glottis. One of the chief advantages of these devices is that limited head, neck, and jaw mobility is less of a concern because of the ability to “look around the corner” of the hypopharynx. Examples in this class are the Bullard (Circon Corporation, Stanford, CT),35-37 WuScope Tubular Fiberoptic Laryngoscope (Achi Corporation, San Jose, CA),38-41 and UpsherScope (Mercury Medical, Inc., Clearwater, FL).42,43 These scopes are relatively expensive and their availability in the ED has been limited.41

**Optical Laryngoscopy** Optical laryngoscopes use a series of lenses to provide a view of the anterior aspect of the glottis that is often not possible with direct laryngoscopy. Although image quality is inferior to that of video laryngoscopes, optical laryngoscopes are inexpensive, durable, and portable tools for difficult airway management. An example is the Airtraq, a disposable optical laryngoscope with a J-shaped blade that allows visualization of the glottis with the head and neck in a neutral position. In small randomized and nonrandomized studies, the Airtraq improved glottic exposure, reduced intubation difficulty scores, decreased cervical spine motion, and caused less change in the heart rate than did direct laryngoscopy with a Macintosh laryngoscope.44-46

**Video Laryngoscopy** Video laryngoscopes use either a micro video camera or more traditional fiber optic bundles encased in a laryngoscope handle design. Placement of the camera is meant to provide a wide-angle view of the glottis but is somewhat more removed from the various debris issues often encountered with the optics-in-the-tube format. The GlideScope (Verathon, Inc., Bothell, WA) is an example of the micro video camera design. This device is relatively new with limited ED experience.47 The literature that exists suggests that it can be used with very little motion of the cervical spine and that glottic visualization is generally excellent.48-51 However, actual intubation may be a bit more of a challenge because it requires an extreme “hockey stick” angulation of the styletted endotracheal tube to reach the glottis. Currently, laryngoscope sizes available correspond roughly to Macintosh No. 4 and No. 2, as well as pediatric sizes.

Additionally, video has been adapted to the more familiar Macintosh blade format in the current C-MAC (Karl Storz, Tuttlingen, Germany). The video element has been shown to improve the grade of view in ED patients52 and in simulated patients with difficult airways.53

**Awake Techniques** In the context of a difficult airway the role of an awake technique may be (1) to determine the status of airway landmarks (with the intention of performing RSI if the landmarks are recognizable) or (2) to perform the intubation given the need for the patient to maintain spontaneous respirations. Either may be accomplished with direct laryngoscopy. A confirmatory look may also be done with a flexible fiberoptic scope.

The term “awake” is a misnomer. It is important to realize that a better descriptor of this concept would be “sedated.” In a patient who is currently maintaining some airway tone and respiratory drive, this approach may be indicated when difficult intubation and ventilation are both anticipated. This approach may be somewhat time consuming because adequate sedation and topical anesthesia of the airway are required (Box 2.3). However, its advantage is that patients will be able to breathe on their own during attempts at definitively controlling the airway. It is important to understand the underlying pathologic process with respect to its dynamic impact on the airway. For instance, a quick look to determine the risks associated with RSI may be misleading if rapid swelling from burns or angioedema are evolving during the process. This

### TIPS AND TRICKS

**GlideScope Use**

The GlideScope handle stays in the midline—no tongue sweep.

The handle is *not* used to lift, unlike a more familiar laryngoscope.

To accommodate the approach to the glottis, the endotracheal tube with stylet will need an acute angle (approximately 90 degrees).

To accommodate advancement of the tube off the stylet, it may help to partially withdraw the stylet during tube advancement. Generally, this last step will require coordination with an assistant.

### BOX 2.3 Patient Sedation and Topical Anesthesia: A Recipe

**Nasal (Anesthesia and Vasoconstriction)**

Only needed if the nasal route is anticipated

- Oxymetazoline (0.05%)/lidocaine (1%), 1:1 in a mucosal atomizer, 10 mL total
- Use preservative-free (cardiac) lidocaine to avoid the rare allergic reaction to preservatives
- Provides effective anesthesia and vasoconstriction
- Time: 2 to 3 minutes

**Oral**

- Lidocaine (4%), 30 mL gargle and spit
- Time: 1 to 2 minutes

**Glottis**

- Lidocaine (1% to 4%, preservative free), 10 mL in a nebulizer
- Time: 10 minutes

**Sedation**

- The goal is only light sedation
- Deep procedural sedation defeats the purpose and may lead to airway obstruction
concept should be kept in mind inasmuch as an initial look may be reassuring but subsequent attempts may be profoundly disappointing because of a dynamic clinical process.

**Blind Nasotracheal Intubation**
The overall success rate of blind nasotracheal intubation is lower than that of RSI.\(^{54,55}\) Additionally, such intubation can be complicated by nasal hemorrhage and induction of vomiting (with its associated risk of aspiration). However, it is often an expedient option in patients who still have fairly vigorous spontaneous respirations.

**Light Wand**
In general, light wand intubation does not rely on visualization of any internal structure. Instead, it relies on a transmitted glow of light through the soft tissues of the neck. The skill required for its application depends largely on recognizing midline (i.e., tracheal) versus lateral soft tissue placement. The Trachlight has been shown to be useful in the operating suite,\(^{56-60}\) but ED experience has been limited. Its design and the necessity for a pronounced L-shaped curve in the stylet and endotracheal tube make it rather forgiving of difficult anatomy that might otherwise inhibit direct laryngoscopy. It is important to note that proper tube placement and preparation of the device do take a few minutes. To make it more useful as a rescue device and more amenable to quick grab deployment, it should be prepared and stored in a ready-to-use condition.

**THE UNANTICIPATED DIFFICULT AIRWAY**
The concept of an unanticipated difficult airway generally presupposes that an attempt at intubation has already been made. It is often a situation that necessitates a change from the original strategy used and requires a fresh perspective. Even though failed intubation attempts are infrequent, they do occur and a rational backup or rescue plan must be in place. Ultimately, the choice of rescue devices is limited by simple availability or experience with use. We will attempt to highlight the various classes of devices that appear promising for use in emergency practice.

The difficult airway and failed airway are related but distinct concepts. A difficult airway becomes a failed airway after three attempts at intubation by a skilled operator. From this point, subsequent maneuvers are in large part directed by operator familiarity and skill. However, the key branch point in the decision-making process depends on the adequacy of ventilation. The “can’t intubate, can ventilate” scenario is managed differently from the “can’t intubate, can’t ventilate” scenario. Each of these situations will be approached within the concept of the failed airway algorithm (Fig. 2.2).

**CAN’T INTUBATE, CAN VENTILATE**
Successful ventilation is defined as being able to maintain oxygen saturation above 90% with bag-mask ventilation. In this situation the provider has some time to direct further efforts and take advantage of any opportunity for success as identified on previous attempts. A directed response might include optimizing or augmenting a previously failed RSI with maneuvers discussed previously. Additionally, it may include the use of alternative intubation devices.

---

**Fig. 2.2 Failed airway algorithm.** BMV, Bag-mask ventilation; BNTI, blind nasotracheal intubation; DL, direct laryngoscopy; EGD, extraglottic device; FO, fiberoptic; ILMA, intubating laryngeal mask airway; RSI, rapid-sequence intubation; VL, video laryngoscopy. (Adapted from Walls RM. The emergency airway algorithm. In: Walls RM, Murphy MF, editors. Manual of emergency airway management. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008.)

**Tracheal Introducer**
The tracheal introducer has been in use since the 1940s, and several products are currently available on the market. The Eschmann introducer is also known as the gum elastic bougie. Incidentally, this term is a misnomer because it is not a bougie (e.g., dilator), nor is it made from gum. Instead, it is a woven Dacron rod 30 cm long that is coated with resin for durability and added stiffness. Newer products have also recently arrived on the market (e.g., Frova, Cook Medical, Bloomington, IN). These introducers are used in conjunction with direct laryngoscopy, especially when the vocal cords cannot be visualized. Their design helps access an extremely anterior trachea and confirm proper placement. One of these design features is an angulated tip that allows directable manipulation and tactile feedback. The tip clicks as it bumps along the anterior tracheal rings. The absence of clicks may suggest esophageal placement. Additionally, if the introducer is in the airway, a hard stop will be felt as the introducer gently passes from the trachea into a small-diameter airway. In contrast, if the introducer is mistakenly placed in the esophagus, the operator will be able to advance the introducer without a firm end point as the introducer enters the stomach.\(^{62-65}\) Once these tactile indicators suggest tracheal placement, a standard endotracheal tube can then be advanced over the introducer and into the trachea.

**The Laryngeal Mask Airway**
The laryngeal mask airway (LMA) currently has several variations in format, one of which, the intubating LMA (ILMA, e.g., Fastrach), is shown in Figure 2.3. This device has been
Fig. 2.3 Intubating laryngeal mask airway (ILMA) (Fastrach). A, The ILMA. B, Place in the oropharynx. C, Position and inflate the ILMA cuff. D, Ventilate the patient with the ILMA. E, Place the ETT into the ILMA. F, Ventilate the patient with the ETT. G, Remove the adaptor. H, Use the stabilizer to remove the ILMA. I, Allow the balloon to pass through. J, Confirm tube placement and ventilate. ETT, Endotracheal tube.
TIPS AND TRICKS

Success with a Tracheal Introducer
Ideal use is when the vocal cords are too anterior to visualize them well with direct laryngoscopy. Have a helper ready to assist in advancing the tube over the introducer. Once the introducer is in trachea, keep the laryngoscope in place and continue lifting. This will straighten the path for the endotracheal tube to slide over the introducer into the trachea. If resistance is met as the endotracheal tube is advanced to the level of the glottis, the tube should be withdrawn slightly, rotated 45 to 90 degrees, and then advanced with gentle pressure.

demonstrated to provide adequate ventilation and a good opportunity for success with blind intubation through the LMA. Placement of the ILMA is nearly identical to that for a standard LMA, with one notable difference: the rigid handle of the ILMA allows easier manipulation of the device and does not require the operator to place fingers inside the patient’s mouth to guide placement. Once the ILMA is placed in the hypopharynx and the cuff is inflated, bag ventilation can begin. If ventilation is adequate (which is the case in the majority of patients and implies good ILMA positioning), the proprietary nonkinking endotracheal tube can be advanced through the lumen of the ILMA. In anesthesia reports such intubation has a high rate of success. The ILMA cuff is then deflated, the ILMA is removed over the endotracheal tube, and the tube is left in place as a definitive airway. The success rate in emergency patients in whom prior intubation attempts have failed and who often have full stomachs is thus far unpublished and unknown.

CAN’T INTUBATE, CAN’T VENTILATE
In this dire situation the vast majority of patients will require an invasive airway unless the expedient use of an extraglottic rescue device can convert the situation to “can’t intubate, can ventilate.”

Rescue Airway Devices
Rescue devices establish an airway for oxygenation and ventilation and sit in an extraglottic position instead of passing through the vocal cords. They are critical tools for the management of difficult and failed airways. The most commonly used extraglottic devices are laryngeal masks (LMA [La Jolla, CA], intubating laryngeal airway [ILA]) and laryngeal tubes (King LT, King Systems, Noblesville, IN; Combitube, Nellcor, Boulder, CO). In emergency airway management, an extraglottic device can be used to provide ventilation until a definitive airway is established, thereby converting a “can’t intubate, can’t ventilate” situation to a “can’t intubate, can ventilate” one. Placement of the extraglottic device and verification of successful ventilation must be done rapidly because failure of the device and worsening hypoxemia would necessitate emergency cricothyrotomy.

The LMA and ILA are two devices designed to create a mask seal over the laryngeal inlet to ventilate and oxygenate patients for short to intermediate periods during elective anesthesia or emergency airway management. The mask portions of each of these devices are similar in shape, but the ILA mask is slightly stiffer to prevent folding of the leading edge during insertion. Many clinicians have familiarity with laryngeal masks, thus making them useful rescue devices. Anesthesia studies report that the ILMA is effective in managing difficult and failed airways, but its performance in ED airway management has not been adequately studied. Several models are commercially available, but only two allow placement of a cuffed endotracheal tube in the trachea through the device (ILMA and ILA) and may therefore be more appropriate as rescue devices in the ED.

An additional type of extraglottic device is a laryngeal tube such as the Combitube and the King LT. These devices have a pharyngeal cuff and an esophageal cuff with a port between the cuffs at the level of the laryngeal inlet for ventilation. The King LT is shorter and simpler than the Combitube, has one large lumen instead of two smaller ones, and uses only one inflation valve to fill both cuffs. Few studies comparing extraglottic rescue airway devices have been performed, and data regarding superiority of one over another as rescue devices are lacking.

Invasive Intubation
Studies done since the common acceptance of RSI in the ED show that approximately 1% of patients at large trauma centers still require cricothyrotomy. These procedures have generally been performed via an open surgical technique. However, newer developments have provided a percutaneous option. The advantage of this technique may lie in its familiarity of use because it relies on the routinely used Seldinger technique.

Several key considerations need to be taken into account with respect to cricothyrotomy. First, it should be recognized that providers are often hesitant to perform what may be perceived as a highly problematic and complicated procedure. In current practice it is not uncommon for the person performing the intubation to be the same individual who needs to recognize failure. Additionally, it is this same provider who will need to change course and provide an invasive airway. In this circumstance, overcoming cognitive inertia can be difficult and contribute to a disastrous delay. Many practitioners say that the most difficult portion of performing a cricothyrotomy is simply making the decision to do so. Such a decision is mandated in a “can’t intubate, can’t ventilate” scenario unless a bridging device can be used successfully. The presence of certain features may influence the actual approach chosen. It should be kept in mind that certain clinical circumstances may make an invasive airway particularly challenging. The mnemonic SHORT (Box 2.4) has been proposed for use when considering an invasive airway. Several technical variants of cricothyrotomy are in common use.

OPEN SURGICAL TECHNIQUE Among the techniques described in the literature, two are commonly referenced. Standard Technique The standard technique generally involves the surgeon being positioned over the right shoulder of the patient. The incision is midline and vertical, and a tracheal hook is placed into the thyroid cartilage. Cephalad traction is applied and a horizontal incision of the cricothyroid membrane is created. Dilatation of the incision is followed by intubation (Fig. 2.4).
CHAPTER 2  •  ADVANCED AIRWAY TECHNIQUES

Fig. 2.4  Standard surgical cricothyrotomy. A, Palpate the cricothyroid membrane. B, Incise the skin vertically and in the midline. C, Identify the cricothyroid membrane. D, Incise the membrane horizontally. E, Use a hook to provide cephalad traction. F, Dilate the stoma vertically. G, Place the tube and rotate it into position. H, Replace the obturator with the inner cannula.

**BOX 2.4 Difficult Cricothyrotomy**

**Mnemonic: SHORT**

- Surgery (i.e., neck scar)
- Hematoma
- Obesity
- Radiation therapy involving the neck with a subsequent scar
- Trauma with disrupted landmarks

---

*Rapid Four-Step Technique*  This technique has evolved from the standard technique for sake of expediency. The procedure is initiated from the head of the gurney, where the intubator is most likely to be positioned. If the pertinent anatomy is clearly palpable (step 1), the skin and cricothyroid membrane are incised simultaneously with a No. 20 scalpel in a horizontal orientation (step 2). A blunt hook is then applied along the caudal side of the scalpel. The hook is used to apply traction to the cricoid ring (step 3). The incision is thus stabilized and widened for subsequent intubation.
PEDIATRIC CONSIDERATIONS

Most of the adjunctive devices discussed in this chapter have limited or no application to young children. There is probably overlap among older children and teens as size allows; however, very little research in this area has been performed. What follows is a brief summary of products that have some applicability to infants and children.

RESCUE DEVICES

**Classic Laryngeal Mask Airway**
No intubating form of the LMA is available for pediatric patients. Although the small adult size might accommodate a larger teen, these devices are scaled to fit on the basis of height considerations. The classic (nonintubating) LMA is available in all sizes appropriate for teens to neonates.

**King LT**
This device in available in sizes appropriate for children, as well as infants.
Fig. 2.6  Percutaneous cricothyrotomy with the Cook (Melker) kit. A, Kit contents. B, Cuffed tube. C, Place the needle through the cricothyroid membrane. D, Place the wire through the needle. E, Incise the skin. F, Thread the dilator/tube over the wire. G, Advance the tube into the airway. H, Remove the dilator and wire.
SECTION I  RESUSCITATION SKILLS AND TECHNIQUES

GlideScope for Children
Currently, a small GlideScope is available for children as small as 2 kg.

Fiberoptics
Flexible fiberoptic scopes have been developed for very small airways. However, the diameter of these scopes is generally too small to allow easy passage of the endotracheal tube off the scope into the airway. This “railroading” method in thinner scopes is more likely to kink the scope. This risks breaking the scopes and is prone to failure.

INVASIVE CONSIDERATIONS
In children younger than 10 years, open cricothyrotomy is contraindicated because of airway size. Currently, the only invasive method that is available for use in young children and infants is needle cricothyrotomy, which is commonly discussed in the context of jet insufflation. Such high-pressure oxygen has been shown to provide adequate short-term oxygenation with somewhat less successful ventilation. This technique does nothing to protect the airway because a cuffed tube is not present in the airway. Various adapted combinations have been described to allow the use of a ventilation bag (plus adaptor) with a cricothyrotomy needle. The pressure generated with such a bag is generally inadequate for all except small infants. In general, jet ventilation catheters such as the VBM catheter (Medizintechnik GmbH, Sulz am Neckar, Germany) are used with high-pressure jet ventilation systems (Fig. 2.7). Barotrauma is often a concern, and kinking or egress of the catheter from its original placement as a result of the high pressure can be an issue. In such a case, manual stabilization of the catheter assembly is prudent until a definitive airway can be established.

Mechanical Ventilation

Jairo I. Santanilla

Alterations in the normal physiology and anatomy of the respiratory system can lead to respiratory failure requiring mechanical ventilation. Anatomic alterations causing airway obstruction, such as tumors, edema, direct or indirect trauma, burns, or other such pathology, may result in respiratory failure. Central nervous system alterations caused by traumatic brain injury, intoxicants, and hemorrhagic or ischemic stroke can cause overt respiratory failure or loss of protective reflexes. Diseases of the peripheral nervous system may result in hypoventilation. Primary pulmonary diseases such as pneumonia can be manifested as ventilation-perfusion mismatch. Asthma and chronic obstructive pulmonary disease (COPD) can lead to hypercapnic respiratory failure. Cardiovascular disease may be accompanied by respiratory failure secondary to acute cardiogenic pulmonary edema, cardiac arrest, myocardial infarction, acute valvular insufficiency, cardiomyopathy, or arrhythmias. Finally, global states such as shock from any cause can lead to respiratory failure.

PRESENTING SIGNS AND SYMPTOMS

Patients requiring mechanical ventilation will typically be seen in extremis. Vital signs are paramount in the initial management. A rapid history and physical examination are also important. Patients may have a wide range of heart rate, respiratory rate (RR), and blood pressure. Pulse oximetry may be difficult to perform. Patients may complain of dyspnea, chest pain, anxiety, or generalized malaise. They may have altered mental status, tachypnea, hypopnea or apnea, diaphoresis, tachycardia, or bradycardia and occasionally arrive in full cardiac arrest. The history and physical examination should be focused on determining the need for mechanical ventilation and the cause of the respiratory failure.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The decision to place someone on mechanical ventilation should be a clinical one performed at the bedside. Five basic questions can assist in determining the need for mechanical ventilation. First, is the patient failing to maintain an adequate

KEY POINTS

- Noninvasive positive pressure ventilation reduces the need for endotracheal intubation.
- Rapid titration and adjustment of the noninvasive ventilator to reduce the work of breathing are essential for the success of noninvasive positive pressure ventilation.
- Monitoring of airway pressure and use of a low-tidal volume strategy minimize the risk for ventilator-induced lung injury.
- Appropriate selection of ventilator mode, tidal volume, positive end-expiratory pressure, fraction of inspired oxygen, and inspiratory flow rate is essential to minimize the work of breathing and enhance correction of hypoxemia.
- Correction of hypoxemia is critical, but correction of hypercapnia is not.

EPIDEMIOLOGY

Patients with severe respiratory complaints account for about 12% of emergency department (ED) visits. Almost 800,000 hospitalizations per year involve mechanical ventilation, which costs nearly $27 billion and represents 12% of all hospital costs. Although the overall number of patients requiring mechanical ventilation is small (2.8%), the relative mortality is as high as 34%. Twenty-six percent of asthmatic patients who required intubation reported the ED as their primary source of health care. Thorough knowledge of noninvasive and invasive mechanical ventilation, lung-protective ventilation strategies, and methods to enhance patient-ventilator synchrony is essential in the practice of emergency medicine.

PATHOPHYSIOLOGY

A wide variety of conditions can lead to respiratory failure. Generally, respiratory failure is characterized as hypoxic (inability to adequately oxygenate), hypercapnic (inability to adequately ventilate), or both hypoxic and hypercapnic. In addition, respiratory failure can be caused by an inability to protect the airway.

Alterations in the normal physiology and anatomy of the respiratory system can lead to respiratory failure requiring mechanical ventilation. Anatomic alterations causing airway obstruction, such as tumors, edema, direct or indirect trauma, burns, or other such pathology, may result in respiratory failure. Central nervous system alterations caused by traumatic brain injury, intoxicants, and hemorrhagic or ischemic stroke can cause overt respiratory failure or loss of protective reflexes. Diseases of the peripheral nervous system may result in hypoventilation. Primary pulmonary diseases such as pneumonia can be manifested as ventilation-perfusion mismatch. Asthma and chronic obstructive pulmonary disease (COPD) can lead to hypercapnic respiratory failure. Cardiovascular disease may be accompanied by respiratory failure secondary to acute cardiogenic pulmonary edema, cardiac arrest, myocardial infarction, acute valvular insufficiency, cardiomyopathy, or arrhythmias. Finally, global states such as shock from any cause can lead to respiratory failure.
airway or protect the airway? Second, is adequate oxygenation being maintained? Third, is adequate ventilation being maintained? Fourth, is the patient's expected clinical course such that intubation is indicated? “Yes” answers to any of these questions should prompt consideration for intubation. Finally, is the patient a candidate for noninvasive positive pressure ventilation (NPPV)? Selected patients may be given a trial of NPPV instead of intubation.

### TECHNIQUES AND METHODS OF MECHANICAL VENTILATION

Mechanical ventilatory support may be provided through a noninvasive or invasive approach. Furthermore, each technique may be applied with a variety of ventilator modes. The key differences in ventilatory support are determined by the trigger, the limit, and the cycle. The trigger is the event that starts inspiration: either patient-initiated or machine-initiated respiratory effort. Limit refers to the airflow parameter that is regulated during inspiration: either airflow rate or airway pressure. The cycle terminates inspiration: either a set volume is delivered (volume-cycled ventilation [VCV]), a pressure is delivered for a set period (pressure-cycled ventilation [PCV]), or the patient ceases inspiratory effort (pressure support ventilation [PSV]).

The plethora of terms associated with mechanical ventilation can cause confusion and misunderstanding, especially because some terms are used interchangeably. Knowing a few simple terms can improve understanding and aid management. The ventilator can be set to reach either a target volume or a target pressure. Other terms used for this target are cycle and limit. Volume cycled, volume limited, and volume targeted all refer to the same thing. Similarly, pressure cycled, pressure limited, and pressure targeted also refer to the same mode. “Control” breaths are ventilator-initiated breaths. “Assist” breaths are patient-initiated breaths. Therefore, a ventilator that is set on volume-targeted (cycled, limited) assist/control (AC) mode has breaths that are initiated by the patient (assist breaths) and the ventilator (control breaths) and reaches a set volume target (cycle, limit).

### MODES OF INVASIVE MECHANICAL VENTILATION

#### CONTROL MODE

Control mode ventilation (CMV) is used almost exclusively in anesthesia, but knowledge of this mode's limitations aids in comprehension of other modes' features (Fig. 3.1). In CMV, all breaths are triggered, limited, and cycled by the ventilator.
In volume-targeted mode, the physician selects a tidal volume (Vt), RR, inspiratory flow rate (IFR), fraction of inspired oxygen (FIO2), and positive end-expiratory pressure (PEEP). The machine then delivers positive pressure and applies as much pressure as required to deliver the set Vt at the set IFR. (In pressure-targeted mode the physician sets the pressure high, RR, FIO2 and pressure low or PEEP.) Note that patients can set their own flow rate in pressure-targeted modes. The machine then delivers positive pressure and applies as much pressure as required to reach the set pressure high. The Vt values generated are a function of respiratory system compliance. The patient is not able to initiate or terminate a breath. If inspiratory effort is initiated before the machine is triggered, the patient is not able to initiate or terminate a breath. If exhalation is incomplete and when the ventilator begins to deliver a breath, this lack of synchrony would cause distress and risk structural lung or airway injury. For these reasons, CMV is never used except for apneic, paralyzed, or anesthetized patients.

ASSIST/CONTROL MODE
AC mode usually provides the greatest level of ventilatory assistance (Fig. 3.2). In volume-targeted ventilation, the physicist sets Vt, RR, IFR, FIO2, and PEEP. (In pressure-targeted mode, the physicist sets the pressure high, RR, FIO2 and pressure low or PEEP.) In contrast to all other modes, the trigger that initiates inspiration can be either an elapsed time interval (determined by the set RR) or the patient’s spontaneous inspiratory effort. When either occurs, the machine delivers the set Vt (in volume-targeted mode) or pressure high (in pressure-targeted mode). The machine follows a time algorithm that synchronizes the machine with patient-initiated breaths. If the patient is breathing at or above the set RR, all breaths are initiated by the patient. If the patient breathes below the set RR, machine-initiated breaths are interspersed among the patient’s breaths. Work of breathing (WOB) is primarily the effort that the patient exerts to cause airway pressure to drop to the threshold that triggers onset of the ventilator. (Manipulating the sensitivity of the ventilator sets this threshold.) Furthermore, WOB may be performed to a variable degree during inspiration, depending on how much the respiratory muscles are activated. WOB with the volume-targeted AC mode may be extreme in two situations: when the Vt drawn by the patient is greater than the set Vt and when the patient inspires at a rate that exceeds the set IFR (see later).

In the majority of situations, AC mode is used as described earlier and is termed volume-targeted or volume-cycled ventilation. As an alternative, some ventilators allow pressure-targeted (cycled) ventilation (PCV, not to be confused with PSV, described later) (Fig. 3.3). Instead of IFR, the limit during PCV is a set airway pressure. Instead of Vt, the cycle during PCV is a set inspiratory time (Ti). On some ventilator models, RR and the inspiratory-to-expiratory (I:E) ratio are set, and Ti is calculated from these settings. On other models, Ti is available as a setting. Because Vt is not set, the Vt delivered varies slightly from breath to breath, depending on lung compliance, airway resistance, and patient effort. PCV may offer a slight advantage over VCV in clinical scenarios that require control of the I:E ratio, but a body of literature investigating this concept does not exist. Historically, PCV was commonly used in neonates and infants, although modern ventilators that precisely measure small Vt are currently favored. PCV may be the only mode available on some portable and transport ventilators.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION AND PRESSURE SUPPORT
Synchronized intermittent mandatory ventilation (SIMV) is probably the most commonly misunderstood mode of mechanical ventilation (Fig. 3.4). The physician sets Vt, RR, IFR, FIO2, and PEEP, as in AC mode. In contrast to AC mode, however, the trigger that initiates inspiration depends on the

---

**Fig. 3.2** Volume-targeted, assist/control mode. Tidal volume is controlled. A minimum mandatory respiratory rate is set and synchronized with patient effort. If the patient breathes at a rate higher than the set rate, all breaths are assisted. The dashed line represents esophageal/intrathoracic pressure dynamics. The first two breaths represent machine-initiated (M) breaths; the second two breaths represent patient-initiated (P) breaths.

**Fig. 3.3** Pressure-targeted, assist/control mode. Inspiratory pressure support (PS) and inspiratory time (Ti) are controlled. Tidal volume may vary from breath to breath. The minimum mandatory respiratory rate is set and synchronizes with patient effort. The dashed line represents esophageal/intrathoracic pressure dynamics. The first two breaths represent patient-initiated breaths; the third breath is a machine-initiated (mandatory) breath. PEEP, Positive end-expiratory pressure.
Volume-targeted, synchronized intermittent mandatory ventilation (SIMV). Tidal volume is controlled only during machine-assisted breaths. Tidal volume may vary during nonassisted (patient-initiated) breaths. The minimum mandatory respiratory rate is set. If the patient breathes more slowly than the set rate, the machine synchronizes with patient effort (third breath). If the patient breathes faster than the set rate, breaths in excess of the set rate are not assisted (second and fourth breaths). M, Machine-initiated breath; P, patient-initiated breath. The dashed line represents esophageal/intrathoracic pressure dynamics.

patient’s RR relative to the set RR. When the patient breathes at or below the set RR, the trigger can be either elapsed time or the patient’s respiratory effort. In this case, WOB is equivalent to AC. When the patient breathes above the set RR, the ventilator is not triggered to assist in making spontaneous breaths in excess of the set RR. The work associated with such breaths may be quite high because the patient must generate enough negative force to pull air through the ventilator and overcome the resistance to airflow caused by the ventilator circuit tubing and the endotracheal tube (ETT), in addition to the WOB required as a result of the underlying disease process.

This limitation of SIMV can be diminished by the addition of PSV (Fig. 3.5). PSV causes inspiratory positive pressure to be applied during patient-initiated breaths that exceed the set RR. The patient initiates and terminates inspiration, thereby determining VT. Once the patient triggers pressure support, it is maintained until the machine detects cessation of patient effort, as indicated by a fall in inspiratory airflow. VT, IFR, and T1 are not controlled but instead are determined by patient effort. The WOB performed during PSV involves triggering the ventilator to deliver the pressure and maintaining inspiratory effort throughout inhalation. Contrast this with machine-assisted ventilation in AC or SIMV, where WOB involves triggering the ventilator but lung inflation continues regardless of the patient’s inspiratory effort. WOB during PSV also depends on the set level of pressure support. Insufficient pressure support is associated with high WOB, which leads to a small VT and a high RR. Adequate pressure support reduces WOB and improves VT and RR. Many experts view RR as the best index of the adequacy of the level of pressure support. It should be adjusted to maintain an acceptable RR of less than 30 but preferably less than 24 breaths per minute.

SIMV can be used in pressure-targeted ventilation. Essentially, the ventilator is set to reach a target pressure for each of the ventilator-initiated breaths and potentially a different target for patient-initiated breaths. Another way to consider pressure-targeted SIMV is as PSV with a set rate.

CONTINUOUS POSITIVE AIRWAY PRESSURE
CPAP alone is not a true form of assisted mechanical ventilation because inspiration is not assisted by increasing airway pressure. Pressure greater than ambient atmospheric pressure is supplied, but it is held constant throughout the respiratory cycle. During inhalation, the gradient between the airway and intrathoracic pressure is higher than it would be if breathing ambient air. Conversely, the gradient is lower during exhalation. As a result, inhalation requires slightly less effort than normal breathing does, and the airways are held open during exhalation to allow better expiratory airflow. As in SIMV, PSV may be added to CPAP. CPAP with PSV is a form of assisted ventilation because inspiratory pressure is augmented, and this is more appropriately referred to as simply PSV. As discussed earlier, the patient initiates and terminates each breath; therefore, WOB is performed as the patient initiates each breath and maintains inspiratory effort throughout inhalation.

OTHER MODES
The most recent innovations in ventilator modes are those that combine volume and pressure targets, which are referred to as dual modes. Pressure-regulated volume control, autoflow, volume ventilation plus, adaptive support ventilation, variable pressure control, and variable pressure support are all dual modes that adjust pressure or volume targets from breath to breath to reach the goals desired. Volume-ensured PSV and pressure augmentation alter parameters within the breath to reach goals. Unfortunately, few studies have compared these latest modes with one another or with conventional modes.

Finally, modes that have rarely been used in the ED setting and are beyond the scope of this chapter include high-frequency ventilation, airway pressure release ventilation, bilevel ventilation, proportional assist ventilation plus, and proportional pressure support.
MONITORING DYNAMIC PRESSURE DURING INVASIVE VENTILATION

Mechanical ventilation can cause damage to the lungs on a macroscopic and microscopic level. The direct cause of lung injury is believed to be a combination of overdistention of the alveoli and repetitive alveolar opening and closing with shear of the alveolar wall. The concept of ventilator-induced lung injury (VILI) has evolved to encompass all forms of injury at the organ and alveolar level, including pneumothorax, pneumomediastinum, bronchial rupture, diffuse alveolar damage, and acute respiratory distress syndrome (ARDS). Pressure is measured at the ventilator end of the circuit (the proximal part of the airway), and this measurement is used as an index of the pressure within the lung.

PEAK INSPIRATORY AIRWAY PRESSURE

Peak inspiratory airway pressure (P_{peak}) is the highest pressure that is generated during inflation of the lung. Because pressure decreases incrementally along the path at each point of resistance, the pressure delivered at the alveolar level may be significantly less than the measured P_{peak} particularly when resistance to airflow is high. Therefore, P_{peak} is not an ideal surrogate measurement for alveolar pressure and does not correlate with VILI.

PLATEAU PRESSURE

Plateau pressure (P_{plat}) is the end-inspiratory airway pressure and is measured just after airflow has ceased. Because this is a static measurement (absence of airflow), resistance of the circuit and airways does not play a role. Therefore, P_{plat} is a logical surrogate measurement for mean alveolar pressure. Its primary limitation is that compliance is not equal in all regions of the lung. The degree of alveolar distention in healthy regions of the lung may be significantly greater than that in heavily diseased lung regions at the same P_{plat}. In a healthy adult undergoing mechanical ventilation with normal lung compliance, P_{plat} is low, usually in the range of 5 to 15 cm H_2O. Patients with alveolar disease (pneumonia, cardiogenic pulmonary edema, acute lung injury [ALI], and ARDS) have poor lung compliance, and P_{plat} is typically much higher in these states. Measures to maintain P_{plat} below the currently recommended limit of 30 cm H_2O are discussed later.

INTRINSIC POSITIVE END-EXPIRATORY PRESSURE

PEEP indicates that the airway pressure measured at the end of exhalation is above ambient air pressure. When PEEP is set by the clinician and applied by the ventilator, it is termed extrinsic PEEP (PEEP_{e}). In contrast, intrinsic PEEP (PEEP_{i}) arises when exhalation is incomplete because of either intrathoracic airway obstruction, early airway closure during exhalation, or inadequate exhalation time. The common end point is trapping of air in the lung at the end of exhalation, which ultimately leads to increased intrathoracic pressure. PEEP, can cause problems through several mechanisms. First, because exhalation is incomplete, air is progressively being trapped in the lungs, thereby leading to early airway closure and dynamic hyperinflation with an associated risk for VILI. Second, PEEP, leads to difficulty triggering the ventilator and increased WOB, as discussed previously. Third, PEEP, can cause patient-ventilator dyssynchrony when the patient continues active contraction of the respiratory muscles at end exhalation as the ventilator is triggered. Lung inflation may begin while the patient is attempting to complete exhalation. Finally, increased intrathoracic pressure can impede venous return to the heart and consequently lead to hemodynamic instability. Simultaneously, impaired venous return may compromise pulmonary blood flow, increase physiologic dead space, and result in worsening hypercapnia. Control of PEEP, is discussed later.

MODES OF NONINVASIVE MECHANICAL VENTILATION

The cause of the respiratory failure is the best predictor of whether a patient will respond to noninvasive techniques. The literature supports the application of NPPV for certain conditions—COPD, asthma, congestive heart failure (CHF), pneumonia, trauma, cancer, and neuromuscular disease—as well as for pediatric patients.

Noninvasive ventilators are more portable because of the use of a smaller air compressor/blower, but they cannot develop pressures as high as larger critical care ventilators can. A noninvasive ventilator can provide up to 20 to 40 cm H_2O of air pressure, as compared with critical care ventilators capable of delivering greater than 100 cm H_2O of air pressure. Newer noninvasive ventilators can be set for volume- or pressure-targeted mode, AC or SIMV, and even proportional assist.

SPONTANEOUS AND SPONTANEOUS/TIMED MODES

In spontaneous mode, airway pressure cycles between inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP). This mode is commonly referred to as biphasic (or bilevel) positive airway pressure, but other proprietary names refer to the same mode. The trigger to switch from EPAP to IPAP is the patient’s inspiratory effort. A variety of ventilator models use one or several of the following to indicate patient effort: a drop in airway pressure, measured inspired volume (usually 5 to 6 mL), or an increase in airflow rate. The limit during inspiration is the set level of IPAP. The inspiratory phase cycles off when the machine senses cessation of patient effort, as indicated by a decrease in inspiratory flow below a set threshold (typically 60% of the peak IFR) or attainment of maximum inspiratory time (usually 3 seconds). The latter is a safety mechanism to prevent lung hyperinflation as a result of ventilator “runaway,” but it was not available on early generations of noninvasive ventilators. VT may vary from breath to breath, dependent primarily on the magnitude and duration of patient effort, but also on lung compliance. WOB is predominantly related to initiating and maintaining airflow throughout the inspiratory phase. Additional WOB may occur if the patient actively contracts the expiratory muscles.

Spontaneous mode is dependent on the patient’s effort to trigger inhalation. Respiratory acidosis will develop in a patient breathing at a slow, inadequate rate. To prevent this adverse consequence, spontaneous/timed mode allows the machine to be triggered either by patient effort or after an elapsed time interval that is calculated from a set minimum.
RR. If the patient does not initiate inspiration during the set interval, IPAP is triggered. For machine-initiated breaths, the machine cycles back to EPAP based on a set inspiratory time. For patient-initiated breaths, the ventilator cycles as it would in spontaneous mode.

Pragmatically, NPPV (noninvasive) and PSV (invasive) are similar but have a few noteworthy differences. First, the trigger for PSV is a drop in airway pressure sensed by the ventilator. Some ventilators monitor airflow in the inspiratory and expiratory limbs of the ventilator circuit and will be triggered if airflow in the inspiratory limb is greater than airflow in the expiratory limb. The sensitivity of the trigger can be adjusted on a conventional ventilator by setting the magnitude of the change in pressure required for triggering. This is contrasted with NPPV, in which sensitivity is continuously and automatically adjusted by the noninvasive ventilator based on the amount of air leak and is not able to be adjusted by the physician. Second, because PSV is supplied by a critical care ventilator, leaks are not tolerated or compensated. Because airflow through a leak may be misinterpreted in this mode as patient inspiratory effort, a leak may lead to early triggering before exhalation is complete. Leaks may also cause failure to cycle off in synchrony with cessation of patient effort. These phenomena are less likely to occur when using a noninvasive ventilator. Finally, the nomenclature used for airway pressure is different. Pressure during the expiratory phase is termed PEEP, analogous to the EPAP of NPPV. Pressure during the inspiratory phase is termed peak inspiratory pressure, analogous to the IPAP of spontaneous mode. The distinction is that in PSV the numerical value for pressure support is the equivalent of the difference between IPAP and EPAP.

INITIATION OF NONINVASIVE POSITIVE PRESSURE VENTILATION

The process of initiating a trial of noninvasive ventilatory support consists of four basic steps. First, the patient must be willing to accept face mask ventilation. Because the patient should remain awake and cooperative during ventilation, the process should be explained before the mask is applied. Initially, an FiO₂ of 100% with 3 to 5 cm H₂O of CPAP is provided. Acceptance may improve if the patient holds the mask against the face. The mask is secured with straps once the patient demonstrates acceptance.

Next, after explaining that the pressure will change, ventilation is switched to NPPV with an EPAP of 3 to 5 cm H₂O and an IPAP of 8 to 10 cm H₂O. IPAP is titrated in 2- to 3-cm H₂O increments until exhaled Vt (measured by the ventilator) is in the range of 6 to 9 mL/kg IBW. Further adjustment of IPAP should be directed toward obtaining an RR of less than 30. Another option is to start with high IPAP (20 to 25 cm H₂O) and titrate down based on patient comfort. Of note, no studies have compared a low-to-high IPAP versus a high-to-low IPAP approach.

EPAP is then adjusted to the lowest level that allows synchrony between the patient and ventilator. Understanding this process requires review of the components of WOB related to triggering the ventilator. The patient activates the inspiratory muscles to decrease intrathoracic pressure. As intrathoracic pressure falls below airway pressure, transpulmonary pressure becomes positive, airflow begins, and the ventilator is triggered. In a normal patient, the inspiratory muscle force required to lower intrathoracic pressure to a level that triggers the ventilator is not great. In a patient with high PEEP, (also known as auto-PEEP), intrathoracic pressure is high at end exhalation. The inspiratory muscle force required to lower intrathoracic pressure below airway pressure is significantly greater. Thus the WOB that is performed to trigger the ventilator is proportional to the amount of PEEP, that is present. While delivering NPPV, it is impossible to measure PEEP without invasive means. Instead, to detect PEEP, signs of difficulty triggering the ventilator or signs of expiratory airflow obstruction should be sought. On physical examination, recruitment of the accessory muscles of inspiration suggests that PEEP, is a problem. A useful technique is palpation of the sternocleidomastoid muscle while simultaneously watching the ventilator flow graphs or listening for the ventilator to trigger. When the muscle is felt to contract before the ventilator triggers, PEEP, may be the culprit. Observation of active abdominal muscle recruitment during exhalation indicates airflow obstruction as a cause of elevated PEEP. When elevated PEEP, is suspected, EPAP should be increased in increments of 2 to 3 cm H₂O until the problem is controlled. The maximum safe level of EPAP that should be used during NPPV has not been determined in an evidence-based manner. Typical initial settings range from 0 to 5 cm H₂O; maximum settings described in the methods sections of various trials range from 12.5 to 15 cm H₂O. It is prudent to measure the heart rate and blood pressure and perform pulse oximetry after each increase in EPAP because high levels may compromise cardiac output. As EPAP is increased, corresponding increasing increments in IPAP are required to maintain a differential between EPAP and IPAP that ensures adequate VT.

Finally, FiO₂ is adjusted to maintain adequate O₂ saturation. In many clinical situations, continuous pulse oximetry alone is adequate for this purpose. Arterial blood gas determinations are not routinely required but may be helpful in select patients to assess improvement in respiratory acidosis.

SPECIFIC DISEASE PROCESSES

CONTROLLING AIRWAY PRESSURE—LUNG-PROTECTIVE VENTILATOR STRATEGIES

Causes of difficulty with mechanical ventilation fall into four general categories:

• High airway pressure during lung inflation
• High PEEP, because of obstructive airways disease
• Patient-ventilator dyssynchrony
• Equipment failure

Acute Respiratory Distress, Acute Lung Injury, and Pulmonary Edema

Elevated plateau pressure is encountered in patients with poor lung compliance as a result of parenchymal lung disease (e.g., pulmonary edema, either cardiogenic or noncardiogenic) or obstructive airways disease with air trapping. The goal is to support the respiratory system while avoiding iatrogenic injury.

Initial studies compared a conventional ventilation strategy (VT of 10 to 15 mL/kg IBW with a goal of obtaining normal PaO₂ and PaCO₂) with a lung-protective ventilation strategy
(Vt of 6 to 8 mL/kg IBW with correction of hypoxia, but allowing hypercapnia in favor of avoiding high airway pressure). The results were conflicting. A landmark study, the ARDS Network Trial, prospectively compared a conventional strategy (Vt of 12 mL/kg and a Pplat limit of 50 cm H2O) with a protective strategy (Vt of 6 mL/kg IBW and a Pplat limit of 30 cm H2O). After enrollment of 861 patients with ARDS and an interim analysis, the trial was stopped early because of a 22% reduction in mortality, 20% fewer days requiring mechanical ventilation, and fewer cases of organ system failure in the group receiving the lung-protective strategy.

The mechanical ventilation strategy in patients with other disease processes has not been studied as extensively. Extrapolation of these findings to patients with CHF, ALI, pneumonia, pulmonary fibrosis, pulmonary contusion, lung cancer, and other lung pathology is not based on experimental evidence.

In summary, based on the available literature, a lung-protective strategy should be used that involves low Vt, limitation of Pplat to 30 cm H2O, and permissive hypercapnia in a patient with ARDS or pulmonary edema to avoid iatrogenic lung injury. This ARDSNet strategy should also be considered in patients with the diffuse infiltrative lung diseases mentioned earlier.

**Obstructive Airways Disease**

Exacerbation of obstructive airways disease requiring mechanical ventilation is often associated with air trapping and dynamic hyperinflation of the lungs. High Ppeak arises as a result of inspiratory airflow resistance, a phenomenon more common in patients with severe asthma than in those with COPD. High Pplat is caused by lung overdistention and consequent diminished compliance. Patients with both high Ppeak and Pplat comprise a group of high-risk patients with both obstruction and overdistention who are at high risk for complications, including pneumothorax, tension pneumothorax, pneumomediastinum, dysrhythmias, and hemodynamic collapse. No prospective trials comparing ventilation strategies in such patients have been conducted. It is common practice to use a strategy of permissive hypercapnia to eliminate PEEP, and avoid high Pplat. This strategy makes use of low Vt, low RR, and high IFR to shorten the inspiratory time and prolong the expiratory time. Although this strategy often leads to hypercapnia, it is considered safer to allow respiratory acidosis to develop than to ventilate at excessive airway pressure. A lower limit of acceptable pH has not been established, but general recommendations have been to allow pH values as low as 7.15 to 7.2. Permissive hypercapnia is required more often in the management of status asthmaticus than in the management of COPD. Evidence in support comes from retrospective studies. Current recommendations include Vt less than 8 mL/kg IBW, an initial RR of 8 to 10 cycles/min, and FIO2 adjusted to obtain a PaO2 of approximately 60 mm Hg or a PaCO2 of 85% to 88%. The concept of permissive hypercapnia and controlled hypoventilation in the management of acute asthma exacerbation has been widely accepted. Some reports suggest that Ppeak and Pplat are not adequate indicators of pulmonary hyperinflation and recommend that expiratory volumes be measured in these patients. This latter technique has not gained widespread acceptance, however.
**Complications**

**Invasive Mechanical Ventilation**
In the ED, complications of mechanical ventilation (Box 3.1) can begin during the preintubation period. Induction agents may cause or worsen hypotension. Overly aggressive bag-valve-mask ventilation may lead to decreased venous return and hypotension. Airway trauma and mechanical complications may be caused by the act of intubation. Initiating mechanical ventilation and transitioning from negative pressure ventilation to positive pressure ventilation may lead to hypotension. Positive pressure ventilation may worsen an existing pneumothorax or give rise to pneumothorax. Auto-PEEP (also known as PEEPi, dynamic hyperinflation, breath stacking) can lead to hypotension and circulatory collapse. Ventilator-associated lung injury can be caused by barotrauma, volutrauma, or trauma related to atelectasis. Long-term complications can include inability to be liberated from the ventilator, ventilator-associated pneumonia, tracheal stenosis, and vocal cord injury.

Some of the commonly underrecognized problems that arise in the support of critically ill patients fall into the category of patient-ventilator dyssynchrony. These situations can markedly increase WOB and lead to increased CO₂ production with both respiratory and metabolic acidosis.

**Intrinsic Positive End-Expiratory Pressure**
Maneuvers directed at elimination of PEEP, have in common the effect of decreasing inspiratory time and therefore providing more expiratory time. Decreasing RR and VT and increasing IFR effectively accomplish this goal. Frequently, this cannot be achieved without sedation, sometimes requiring the addition of pharmacologic paralysis.

**Difficulty Triggering the Ventilator**
To trigger a ventilator, a patient must cause either a drop in pressure or an increase in airflow at the proximal part of the airway, depending on the type of ventilator in use. The magnitude of change required to trigger the ventilator is adjusted by setting the sensitivity, usually in the range of −1 to −2 cm H₂O below the level of PEEP. Difficulty triggering the ventilator is often not easy to detect. When it becomes obvious by physical examination that the patient is using the accessory muscles of respiration to trigger the ventilator, the problem may be severe. The condition can be detected earlier by inspecting the pressure-volume time curve on the ventilator display. A large negative deflection at the beginning of inhalation suggests that ventilator sensitivity needs to be increased.

More commonly, high PEEP, is the cause. The patient must first lower intrathoracic pressure enough to overcome PEEP, before airway pressure can drop to the threshold sensitivity. The solution to this problem is to raise PEEP, to a level one half to three fourths of PEEP, and allow the patient to perform less work to trigger inhalation. This process mandates frequent reassessment of PEEP, and manipulation of the ventilator during this dynamic period.

**Autocycling**
Autocycling refers to a phenomenon in which the ventilator set in AC mode begins to rapidly trigger without the patient initiating respiration. The cause is usually vacillations in airway pressure that the ventilator interprets as patient effort. Tremors, shivering, voluntary motion, convulsions, and oscillating water in the ventilator circuit are all examples of potential causes. Autocycling should prompt immediate disconnection from the ventilator circuit and ventilation with a bag-valve device until the problem has resolved.

**Rapid Breathing**
When attempting to ventilate a patient with an obstructive process, the goal is to eliminate PEEP. Permissive hypercapnia is best achieved at low RR, but at the same time hypercapnia is a powerful stimulus to breath. This can typically be quelled by using a combination of sedatives such as benzodiazepines in combination with opiates. Neuromuscular blockade should be considered a last resort undertaken only after careful consideration of the risks associated with prolonged paralysis and the potential development of neuropathy in patients with critical illness. If undertaken, it should be done only to weaken the patient sufficiently to inhibit dysynchrony with the ventilator. Other common causes of rapid breathing include sepsis, pulmonary emboli, pregnancy, hepatic encephalopathy, intracranial hypertension, stroke or hemorrhage, and posthypercapnic status. Some of these conditions are appropriate physiologic responses, whereas others, though pathologic, are difficult to control and occasionally tolerated.

**Outstripping the Ventilator and Double Cycling**
In patients undergoing low-VT ventilation for ARDS or for an obstructive process, hypercapnia and an increased respiratory drive will develop. Outstripping the ventilator refers to the patient’s effort to draw a higher VT than is set while in a volume-targeted mode. This can be detected by observing the exhaled VT or by finding a negative deflection at the end of inhalation on the pressure-volume time plot. Double cycling occurs when the patient desires a larger VT than is set and continues to inspire despite the delivery of a breath. The ventilator will then provide a second breath almost immediately after the first. This is especially problematic because the actual VT delivered is twice the set volume. As with controlling rapid breathing, the solution is sedation and analgesia, particularly with opiates. In addition, switching to a pressure-targeted mode or increasing the set VT may alleviate this issue.

PEEP, Positive end-expiratory pressure.
**Straining over the Ventilator**

Straining over the ventilator indicates that the patient is attempting to inhale at a flow rate in excess of the set IFR on a volume-targeted mode. When it is obvious by examination that the patient is actively inhaling, the problem may be severe. On the pressure-volume time plot the rise in pressure during inhalation will be concave rather than convex. Potential solutions are to raise the IFR, switch to pressure-targeted mode or PSV, or use sedation and analgesia.

**Coughing**

Coughing is a common problem that can arise from increased secretions, a foreign body in the airway (ETT), or the underlying pulmonary disease process. Coughing can lead to autocycling, poor patient comfort, ETT dislodgment, and rarely airway injury. Placement of the ETT above the carina should be confirmed. Suctioning plus provision of warmed, humidified air is often helpful. If these simple measures fail to provide relief, aerosolized lidocaine or suppression with opiates may increase patient comfort.

**EQUIPMENT FAILURE**

Whenever a patient decompensates while receiving mechanical ventilation, consideration should be given to equipment failure as the cause. Interruption of the oxygen supply, accidentally rotated knobs, disconnected ventilator circuitry, and obstructed tubes are all potential culprits. Immediate action should include disconnection from the ventilator and bag ventilation with 100% O₂. The mnemonic made popular by the American Heart Association’s Pediatric Advanced Life Support Course is useful to recall the causes of unexpected decompensation: DOPE (dislodgment of the ETT, obstruction of the tube, pneumothorax, and equipment failure). Confirmation of ETT placement, suctioning via an endotracheal catheter, auscultation, chest radiography, and equipment troubleshooting are necessary actions.

**NONINVASIVE MECHANICAL VENTILATION**

The main complication of NPPV is an inability to tolerate the mask or the pressure. Long-term complications can include an inability to eat or drink, nasal and oral dryness, and pressure necrosis on the bridge of the nose, the cheeks, or the chin or above the ears.

---

**PROGNOSIS**

Because of the wide range of causes of respiratory failure, the prognosis is highly variable and dependent on the cause and severity. The prognosis of patients with respiratory failure caused simply by oversedation from intoxicants can be quite good. Conversely, patients with ARDS as their sole organ dysfunction have a mortality of 20% to 25%. Respiratory failure with multiorgan system failure carries much higher mortality that is based on the severity of the illness. Overall, a requirement for invasive mechanical ventilation carries an approximate 34.5% in-hospital mortality.

---

**TIPS AND TRICKS**

**Pitfalls and Pearls for Mechanical Ventilation**

**Pitfalls**

- Not considering NPPV
- Not using NPPV early enough
- Not having the personnel or time to adequately monitor and make adjustments
- Not adjusting pressures quickly enough

**Pearls**

- Early use of NPPV should be considered in a wide variety of patients.
- Proper patient selection is paramount.
- Selection of the interface and adjustment of parameters are crucial for success.
- A team approach with close observation of the patient is vital.

Normal organ function requires adequate perfusion and delivery of oxygen. Oxygen delivery is determined by arterial oxygen content and cardiac output. Arterial oxygen content is a function of hemoglobin concentration and arterial oxygen saturation. Cardiac output is governed by heart rate, contractility, and loading conditions. Any process that adversely affects cardiac output or arterial oxygen saturation can decrease oxygen delivery and result in circulatory dysfunction.

Cardiac output can be affected by the heart rate, arrhythmias, and alterations in ventricular loading. Preload, afterload, and contractility each affect ventricular loading. The Frank-Starling law (Fig. 4.2) states that the principal force governing the strength of ventricular contraction is the length of muscle fibers. In a normal heart, muscle fiber length is determined by intravascular volume, often termed preload. As preload increases, myocardial fibers increase in length, which results in increased force of contraction. Increased force of ventricular contraction increases stroke volume and cardiac output. In contrast, depletion of intravascular volume results in muscle fiber shortening, less forceful cardiac contractions, lower stroke volume, and decreased cardiac output.

Increasing ventricular preload improves myocardial contractility only to a point, beyond which myocardial fibers become overstretched. Overstretched fibers can lead to worsening myocardial contractility and, eventually, increased hydrostatic pressure and interstitial edema (e.g., pulmonary edema).

Changes in afterload can also affect ventricular function. For example, severe hypertension impedes ventricular function by reducing cardiac emptying and flow while increasing myocardial workload. Similarly, reducing afterload increases cardiac emptying and flow while decreasing myocardial workload.

Contractility, a measure of ventricular function, is altered by a variety of factors. Medications such as dobutamine can increase the force of contraction for a given preload. In contrast, diseases such as congestive heart failure can reduce contractility and worsen stroke volume and cardiac output.

Circulatory dysfunction can also occur with alterations in regional or microcirculatory blood flow. Disorders that affect arteriolar tone, such as sepsis, cause maldistribution of blood flow between organs and a mismatch of oxygen delivery with demand. Capillary obstruction and endothelial impairment interrupt intraorgan oxygen delivery, thereby potentially resulting in organ failure.

Circulatory dysfunction exists as a spectrum ranging from mild impairment to shock with overt circulatory collapse. Shock is defined as the inability of the circulatory system to...
provide adequate tissue perfusion, which potentially leads to cellular dysfunction. Four categories of shock have been differentiated and defined by the underlying pathophysiology of the circulatory dysfunction: hypovolemic, cardiogenic, distributive, and obstructive (Box 4.1). Because each category requires specialized management, every attempt must be made to determine the exact cause of the shock.

**PRESENTING SIGNS AND SYMPTOMS**

Circulatory insufficiency can be accompanied by myriad clinical findings. The signs and symptoms primarily reflect organ dysfunction secondary to hypoperfusion and decreased oxygen delivery. Classic signs of circulatory dysfunction include reduced blood pressure, abnormal heart rate, tachypnea, hypoxemia, mottled extremities, and decreased urine output. The most dramatic manifestation is cardiac arrest with complete circulatory failure. Unfortunately, many emergency department (ED) patients with circulatory dysfunction have vague, nonspecific symptoms. Common nonspecific symptoms of circulatory insufficiency include fatigue, malaise, weakness, lightheadedness, dizziness, altered mental status, diaphoresis, dyspnea, and syncope. Circulatory dysfunction should be considered in every patient with vague, undifferentiated symptoms.

**INITIAL ASSESSMENT**

An initial circulatory assessment should be performed for every ED patient within the first minutes after arrival. This assessment consists of a review of triage vital signs, a focused history, physical examination, and possibly bedside ultrasonography. The goal of the initial circulatory assessment is to detect signs of organ hypoperfusion and identify any immediately life-threatening disorders. Life-threatening disorders requiring rapid diagnosis and treatment include pulmonary embolism, acute myocardial infarction, cardiac tamponade,
SECTION I  RESUSCITATION SKILLS AND TECHNIQUES

Blood Pressure

Blood pressure, the driving force for organ perfusion, is determined by cardiac output and arterial tone. It is important to understand that no blood pressure value is considered normal for every patient. Normal blood pressure values do not always indicate sufficient oxygen delivery. Blood pressure values should be interpreted in the context of the patient’s clinical findings, medical history, and treatment received.

Blood pressure is one of the most common measurements in all of clinical medicine, yet it is often measured incorrectly. In the ED, blood pressure is initially obtained during triage with automated blood pressure devices that apply the oscillometric method. These devices can be adversely affected by ambient noise and cuff position. In addition, automated devices typically overestimate true arterial blood pressure in patients with low-flow states. These limitations, combined with activity in the triage environment and patient anxiety, often result in inaccurate measurements of blood pressure. Understandably, triage values can be an unreliable indicator of true blood pressure. Blood pressure measurements should be repeated serially at the bedside in patients demonstrating any evidence of circulatory insufficiency.

The auscultatory method has long been considered the “gold standard” for noninvasive blood pressure measurement. It determines systolic and diastolic pressure on the basis of detection of Korotkoff sounds. The ideal location is the upper part of the arm. The procedure is performed as follows:

1. Remove all clothing from the arm and place the blood pressure cuff so that the middle of the cuff is approximately at the level of the right atrium. The lower edge of the cuff should be 2 to 3 cm above the antecubital fossa to allow easy palpation and auscultation of the brachial artery.
2. Locate the radial artery and inflate the blood pressure cuff to approximately 30 mm Hg above the point at which the radial arterial pulse disappears.
3. Place the bell of the stethoscope over the brachial artery and deflate the cuff at a rate of 2 to 3 mm Hg per second. The appearance of faint, repetitive sounds for at least two consecutive beats is phase I of the Korotkoff sounds. Phase I is systolic blood pressure. The point at which all sounds disappear is phase V, or diastolic blood pressure.

Measure blood pressure bilaterally during the initial circulatory examination. A difference of more than 10 mm Hg is significant and may indicate an aortic emergency. Unfortunately, up to 20% of individuals have significant blood pressure differences between their arms. Nevertheless, an aortic emergency must be ruled out in any patient with evidence of circulatory insufficiency and blood pressure discrepancies.

Though considered the gold standard, the auscultatory method has several pitfalls. Box 4.2 lists errors commonly made during measurement of blood pressure with the auscultatory method.

Heart Rate

The heart rate is an integral component of cardiac output. Tachycardia or bradycardia can impair circulatory function. As with blood pressure, triage measurements of the heart rate...
BOX 4.2 Pitfalls in Blood Pressure Measurement Using the Auscultatory Method

Failure to use an appropriately sized blood pressure cuff:
- Blood pressure is falsely elevated if the cuff is too small.
- The bladder should measure at least 80% of the length and be 40% of the width of the upper part of the arm.
- Use a thigh cuff if necessary.

Failure to recognize the auscultatory gap:
- Occurs in elderly hypertensive patients with wide pulse pressure.
- Results in overestimation of diastolic pressure.
- Auscultation should be continued until the cuff is fully deflated.

Hypotensive states:
- The auscultatory method overestimates blood pressure in low-flow states.
- Do not use the auscultatory method to monitor unstable patients.

can be inaccurate and unreliable. Therefore, heart rate measurement should be repeated in every patient on initial examination. In addition to the rate, irregularities in rhythm should be noted. Arrhythmias can severely compromise circulatory function and organ perfusion. Furthermore, heart rate variability may be an early indication of circulatory dysfunction. Methods to determine heart rate variability remain investigational and require additional research before clinical application.

Orthostatic Blood Pressure

Depletion of intravascular volume can impair oxygen delivery by decreasing venous return and cardiac output. Symptoms of volume depletion are attributable to reduced cerebral blood flow and include weakness, lightheadedness, unsteadiness, impaired cognition, tremulousness, and syncope. Orthostatic blood pressure measurements can occasionally aid the EP in detecting otherwise unsuspected intravascular volume depletion, but they must be integrated with specific clinical findings. They are not obtained routinely because they have significant limitations.

A positive orthostatic blood pressure response is defined as a reduction in systolic blood pressure of at least 20 mm Hg or a reduction in diastolic blood pressure of at least 10 mm Hg within 3 minutes after standing in a patient with symptoms of volume depletion. Orthostatic blood pressure should be measured with the patient in the supine and standing positions. For patients who are unable to stand or who are markedly unsteady, a sitting position may be used. Wait at least 2 minutes before obtaining a standing blood pressure measurement because nearly all patients have a brief orthostatic response immediately on standing. Always measure the heart rate with orthostatic blood pressure. In normal patients, the heart rate increases from 5 to 12 beats/min with standing. Increases greater than 30 beats/min are abnormal and indicate significant volume depletion.

Orthostatic blood pressure measurements have several limitations. Numerous conditions in addition to volume depletion impair the postural hemodynamic response and result in orthostatic hypotension. Most notable are the effects of aging and medications. Up to 30% of elderly patients demonstrate an orthostatic response in the absence of volume depletion. Many elderly patients take medications that alter the postural response to changes in position; such medications include antiadrenergics, antidepressants, antihypertensives, neuroleptics, anticholinergics, and antiparkinsonian drugs. In addition, any disorder causing primary or secondary autonomic dysfunction can lead to orthostatic hypotension.

Pulse Pressure

Increasing evidence demonstrates that abnormal pulse pressure—the difference between systolic and diastolic blood pressure—is an independent risk factor for cardiovascular morbidity and mortality. To date, studies have focused on outpatients with established hypertension. Nevertheless, it is important to determine pulse pressure in the initial circulatory assessment of an ED patient. Acute disorders that alter circulatory function are often manifested as abnormalities in pulse pressure. A narrow pulse pressure (<40 mm Hg) indicates reduced stroke volume and thus reduced cardiac output. Life-threatening conditions resulting in a narrow pulse pressure include tension pneumothorax, cardiac tamponade, pulmonary embolism, acute myocardial infarction with cardiogenic shock, and severe volume depletion. A widened pulse pressure (>40 mm Hg) results from processes that lower systemic vascular resistance. Diseases that can be accompanied by widened pulse pressure include sepsis, anaphylaxis, acute aortic insufficiency, adrenal insufficiency, and neurogenic shock.

HISTORY

A focused history is essential during the initial circulatory assessment. Key elements are a history of the present illness, previous medical history, medication history, family history, and social history. With respect to the history of the present illness, determine the onset and duration of symptoms, the context in which the symptoms developed, any associated symptoms, and any aggravating or alleviating factors. Important associated symptoms include chest pain, dyspnea, palpitations, syncope, and altered mental status. Review the patient’s medical history and direct attention to disorders that may impair cardiac output or arterial oxygen content.

Medications can result in circulatory abnormalities through direct effects or side effects. Two important classes of medications are antiarrhythmic agents and antihypertensive agents. It is crucial to note whether the patient is taking a beta-blocker or calcium channel blocker because both agents can alter the compensatory response to circulatory insufficiency. Always interpret vital signs in the context of the medical history and medication regimen.

Additional key components of the history are the family and social histories. Directly question patients about their family history of sudden death, premature coronary artery disease, venous thromboembolism, and connective tissue disorders (e.g., Marfan syndrome). Similarly, question patients about their use of illicit substances known to have circulatory effects, namely, cocaine.

PHYSICAL EXAMINATION

Physical examination of the circulatory system begins with the general appearance of the patient. Observe the patient’s positioning, mental status, skin color, and respiratory pattern.
Suspect circulatory abnormalities in restless, diaphoretic, delirious, pale, mottled, or tachypneic patients. In addition, note any distinct clinical features implying an underlying medical condition. Table 4.1 lists the characteristic features of disorders that can affect the circulatory system.

Examine the head and neck for abnormalities suggesting circulatory disease. Facial edema implies impaired venous return resulting from conditions such as superior vena cava thrombosis and constrictive pericarditis. Examination of the jugular venous pulse provides important information about central venous pressure (CVP) and the dynamics of the right side of the heart.9 Place the patient in a 45-degree recumbent position and shine a light tangentially across the neck. The right side is preferred because of its anatomic alignment with the superior vena cava and right atrium. Beginning at the sternal notch, measure the height (in centimeters) of the internal jugular vein pulsations. Pulsations more than 4 cm above the sternal notch are abnormal and a sign of elevated CVP.9 Figure 4.3 illustrates jugular venous distention in a young woman with pericardial effusion.

The cardiopulmonary examination is a quintessential component of circulatory assessment. Observe the rate, depth, and effort of respirations. Tachypnea accompanied by shallow respirations or the use of accessory muscles indicates impending respiratory failure. Auscultate the lungs for asymmetric breath sounds, rhonchi, rales, and wheezing. Recall that any pulmonary process can adversely affect arterial oxygen content and thereby impair oxygen delivery. Auscultate the heart over the right and left upper sternal edges, the lower left sternal edge, and the cardiac apex. Determine the rate and listen for rhythm irregularities, the intensity of heart sounds, murmurs, gallop rhythms, and pericardial rubs. Though difficult with the ambient noise in the ED, attempt to determine whether cardiac murmurs are systolic or diastolic, which can potentially provide valuable information in patients with acute cardiopulmonary dysfunction. Gallop rhythms are low-frequency heart sounds that are heard best with the bell of the stethoscope.

The extremities must be examined as part of the initial circulatory assessment. It is important to observe their color

and temperature. Signs of poor perfusion include cold, pale, clammy, mottled skin associated with delayed capillary refill (normal capillary refill is less than 2 seconds). Inspect for symmetric or asymmetric edema and clubbing of the fingers and toes. Finally, palpate the carotid, radial, femoral, dorsalis pedis, and posterior tibial pulses for rate, amplitude, and regularity.

**EMERGENCY ULTRASONOGRAPHY**

Even after the most careful evaluation of the history, vital signs, and physical examination, the pathophysiology of the circulatory dysfunction may not be completely clear. In this situation, further diagnostic testing is needed to confirm a diagnosis or initiate treatment. Unfortunately, diagnostic testing may require transfer of the patient from the ED to areas in the hospital with significantly less monitoring (e.g., the radiology suite).

Over the past 3 decades, ultrasonography has become essential in the initial assessment of patients with circulatory dysfunction. Ultrasonography is easily performed at the bedside and provides a noninvasive, real-time assessment of causes of circulatory dysfunction. Because ultrasonography may identify the cause of circulatory dysfunction faster than traditional diagnostic testing can, definitive interventions can be initiated rapidly, thereby potentially minimizing end-organ damage.

Many ultrasonography algorithms and approaches for assessing circulatory dysfunction have been published. For the purposes of this discussion, we will use the RUSH (Rapid Ultrasound in Shock) protocol to illustrate the utility of ultrasonography in evaluating circulatory dysfunction. In three systematic steps, the RUSH protocol evaluates circulatory dysfunction as follows:

Step 1: Evaluate the heart (the “pump”).
Step 2: Assess intravascular volume status (the “tank”).
Step 3: Evaluate the major vascular structures (the “pipes”).

**Step 1: Evaluate the Pump**

Evaluation of the heart with the RUSH protocol is different from a formal echocardiogram obtained by cardiologists. Formal echocardiography examines the heart from multiple views, comments on segmental wall motion abnormalities, and evaluates valvular function and structure. The cardiac component of the RUSH protocol is limited to the following: (1) global left ventricular function, (2) relative size of the left ventricle (LV) to the right ventricle (RV), and (3) evaluation of the pericardial sac for tamponade (Fig. 4.4). To perform the assessment, a 3.5-MHz probe is placed on the left anterior aspect of the chest (i.e., parasternal view) (Fig. 4.5, A) or below the costal margin (i.e., subcostal view) (Fig. 4.5, B). Once an adequate view is obtained, global left ventricular function can be described as normal, hyperkinetic, reduced, or severely reduced.

The next cardiac assessment is left and right ventricular size. In normal patients, the RV is 60% the size of the LV. Any increase in the ratio of RV to LV size is considered abnormal and suggests the possibility of pulmonary embolism or right ventricular infarction as the cause of the circulatory dysfunction. In these situations, the thin-walled RV can fail under acutely increased pressure or volume loads. If right ventricular failure occurs, the amount of blood delivered to the left
side of the heart may not be sufficient for adequate cardiac output.

The final portion of the cardiac examination is evaluation of the pericardial space. Pericardial tamponade can cause obstructive shock and should be diagnosed promptly. The classic echocardiographic images show a large anechoic space (i.e., fluid) around the pericardium that is compressing the RV and can lead to a hyperdynamic and underfilled LV.

**Step 2: Evaluate the Tank**
The second step in the RUSH protocol is evaluation of intravascular volume status, or “the tank.” As stated previously, depletion of intravascular volume reduces preload and decreases left ventricular filling, thereby decreasing cardiac output. Examination of the inferior vena cava (IVC) from a subcostal approach allows evaluation of the tank. For example, a patient with hypovolemic shock may have a small IVC that changes significantly in diameter with respiration. Such a patient probably has low CVP with an empty tank, thus indicating that volume should be administered as part of the resuscitation. Contrast this example with a patient with a full tank; that is, a large and dilated IVC. This condition may occur in cardiogenic or obstructive shock, where volume may assist in resuscitation, but would probably not be the main cause of the underlying pathophysiology.

Following determination of intravascular volume, assess the “leakiness” of the tank; that is, examine major body compartments where fluid may have “leaked.” Examination of the abdominal compartment and the thoracic space for free fluid may reveal the source of leakiness (Fig. 4.6). Finally, evaluation for the presence of pneumothorax is critical in assessment of the tank because tension pneumothorax can cause obstructive shock secondary to compression of the major vessels and relative hypovolemia and shock.

**Step 3: Evaluate the Pipes**
The final step in the RUSH protocol is evaluation of the “pipes”; that is, examination of the major arteries and veins for rupture or obstruction. Inspect the thoracic and abdominal portions of the aorta for dissection or aneurysm. Then focus on the venous system and look for deep vein thrombosis (DVT) by compressing the veins of the lower extremity. Hypotensive patients with evidence of DVT may have a hemodynamically significant pulmonary embolus.

All three steps of the RUSH protocol should be completed sequentially and thoroughly. If an abnormality is found, the temptation to terminate the study early should be avoided because of the potential for additional findings. Once the examination has been completed, positive and negative findings should be clinically integrated and interpreted to determine the cause of the shock. Combined findings from the RUSH evaluation and their indication of the type of shock are listed in Table 4.2.

**Additional Uses of Emergency Ultrasonography**
Ultrasonography can be used for emergency procedures such as establishment of intravenous access, pericardiocentesis, and transvenous cardiac pacing.\(^1\)\(^2\) It can also be used for hemodynamic monitoring (e.g., volume responsiveness, CVP, pulmonary artery occlusion pressure [PAOP], cardiac output).\(^1\)\(^3\)\(^4\)

**PROCEDURES AND CIRCULATORY MONITORING**
Procedures pertinent to circulatory assessment and support center on obtaining vascular access and placing invasive circulatory monitors. Rapid attainment of intravenous access is required for patients exhibiting signs and symptoms of hypoperfusion. Invasive circulatory monitoring is used to ensure adequate tissue perfusion and oxygen delivery. Invasive monitoring is indicated for patients who continue to exhibit signs of hypoperfusion despite initial resuscitative measures. Common invasive modalities include arterial blood pressure monitoring, CVP monitoring, and pulmonary artery catheterization. A number of new monitoring modalities have been developed to evaluate the adequacy of circulation. These new modalities include esophageal Doppler analysis, pulse contour analysis, thoracic bioreactance, near-infrared retinal spectroscopy, transcutaneous tissue oxygen monitors, central venous oxygen saturation monitoring, and sublingual capnometry.

**INTRAVENTRIOUS ACCESS**
Despite the physician’s desire to perform central venous catheterization during initial resuscitation, peripheral venous cannulation is preferred. As stated by Poiseuille’s law, the rate at which intravenous fluids can be infused depends on the radius and length of the catheter. Greater volume can be infused over a shorter time with short peripheral catheters than with a central venous line. Peripheral catheters should be 18 gauge or larger. The external jugular veins and the veins of the antecubital fossa provide rapid and safe access for peripheral venous cannulation.

Central venous catheterization has become a common bedside procedure in emergency medicine. In the United States, more than 5 million central venous catheters are placed each year. Table 4.3 lists several indications for and contraindications to establishing central venous access. The procedure presents a risk for a number of complications (see the

![Fig. 4.6](image-url) Free fluid in the thoracic space as demonstrated by bedside ultrasound.
CHAPTER 4

SHOCK

Red Flags box), but their occurrence can be minimized by following the basic rules of good practice (see the Tips and Tricks box). For catheterization of the internal jugular vein, the ultrasonography probe should be positioned on the anterior aspect of the neck, as demonstrated in Figure 4.7. Identification of the vein can be facilitated by asking the patient to perform the Valsalva maneuver, which causes engorgement of the neck veins (Fig. 4.8, A and B).

ARTERIAL BLOOD PRESSURE MONITORING

Invasive arterial blood pressure monitoring is required for patients with persistent circulatory dysfunction despite initial resuscitative measures. Primary indications for placement of an arterial line include continuous blood pressure monitoring, the need for frequent blood sampling, and serial measurements of PaO₂. When possible, the radial artery should be used for this purpose. It offers the advantages of a peripheral position and easy compressibility in the event of unsuccessful cannulation. Additionally, the nearby ulnar artery supplies collateral blood flow to the hand while the radial artery is cannulated. If the radial artery cannot be used, a line can be placed in other arteries, as listed in Box 4.3.

Catheter placement is guided by palpation of the artery. When the pulse is difficult to detect, ultrasound becomes an important aid for visualization of the target artery. Cannulation of the radial artery under ultrasound guidance is faster, requires fewer attempts, and is associated with fewer complications than the palpation method is. Proper patient positioning for radial artery cannulation is illustrated in Figure 4.9.

**Central Venous Pressure**

CVP is intravascular pressure in the central vena cava system, near its junction with the right atrium. Clinically, CVP is used as a marker of volume status and cardiac preload. Normal values for CVP range from 8 to 12 mm Hg. CVP can be estimated noninvasively by examining the internal jugular vein (as described in the physical examination section of this chapter), but bedside determinations have been shown to be inaccurate and unreliable. Direct measurements, through a subclavian or internal jugular vein catheter, provide more reliable results. CVP can be measured via a femoral central venous catheter; however, values typically differ by 0.5 to 3 mm Hg from those obtained from the superior vena cava. In a patient who is not mechanically ventilated, CVP can be estimated noninvasively by visualizing the IVC with ultrasound (Table 4.4). For example, a normally sized IVC that collapses more than 50% correlates with a CVP between 0 and 5 mm Hg.
SHOCK
cannulation. The decrease in patency of the line and maintenance of its complications—mixed venous oxygen saturation, and intrapulmonary vascular measurements obtained with pulmonary artery catheterization—is considered the gold standard for circulatory monitoring in the critically ill. Circulatory monitoring in specific vascular beds. These promising modalities detect hypoperfusion and impaired oxygen delivery directly, it would seem to be an invaluable tool for circulatory monitoring. Unfortunately, routine use of this type of catheter remains controversial. Use of a pulmonary artery catheter has not been shown to decrease patient morbidity or mortality rates. In fact, use of a pulmonary artery catheter may be detrimental. Complications of insertion include pneumothorax, ventricular arrhythmia, ventricular perforation, and pulmonary artery rupture. Until further evidence is published, pulmonary artery catheters should not be used in the ED for assessment and support of the circulatory system.

**ADDITIONAL CIRCULATORY MONITORING MODALITIES**
The circulatory system can also be assessed with global, or tissue, markers of hypoperfusion. Methods of assessing global hypoperfusion in the ED include central venous oxygen saturation and serum lactate values. Under normal circumstances, cells extract 25% to 30% of the oxygen from the circulation. Therefore, blood returning to the central circulation has an oxygen saturation ranging from 70% to 75%. When the circulation fails to deliver adequate oxygen, cellular oxygen extraction is increased. This increase is reflected as decreased mixed venous oxygen saturation, measured via a pulmonary artery catheter. Mixed venous oxygen saturation values of less than 65% are associated with decreased perfusion and oxidative impairment of some vascular beds. Central venous oxygen saturation of less than 70%, measured intermittently or continuously via a central venous catheter, is a reliable surrogate for mixed venous oxygen saturation. Central venous oxygen saturation, as a global marker of hypoperfusion, was used in a landmark study that demonstrated a significant decrease in mortality rate in ED patients with sepsis in whom that marker was used. Central venous oxygen saturation values should be obtained from either subclavian or internal jugular central venous catheters.

Serum lactate values are also used as global markers of hypoperfusion. With persistently impaired oxygen delivery, cells convert to anaerobic metabolism, which results in the accumulation of lactic acid. A lactate level higher than 2 mmol/L is considered an indicator of inadequate oxygenation. Abnormal lactate levels have numerous causes, but the clinician should always regard impaired tissue perfusion as the primary cause in an ED patient.

The trend in lactate values is the most clinically useful information. Increasing serial lactate levels portend a worse prognosis and indicate a persistent circulatory dysfunction. A 10% reduction in lactate concentration in serial samples may be a more clinically useful marker of resuscitation than central venous oxygen concentration.

Tissue-specific monitors of hypoperfusion include gastric tonometry, sublingual capnometry, near-infrared spectroscopy, and tissue oxygen tension. These circulatory monitoring modalities detect hypoperfusion and impaired oxygen delivery in specific vascular beds. These promising modalities require further prospective investigation and are not used in the daily practice of emergency medicine. Available noninvasive methods for measuring cardiac output include esophageal Doppler ultrasonography, impedance plethysmography, and

**PULMONARY ARTERY CATHETERIZATION**
First described by Swan and colleagues in the early 1970s, pulmonary artery catheterization is considered the gold standard for circulatory monitoring in the critically ill. Circulatory measurements obtained with pulmonary artery catheterization include cardiac output, right ventricular ejection fraction, mixed venous oxygen saturation, and intrapulmonary vascular pressure. From these measurements, oxygen delivery, oxygen consumption, systemic vascular resistance, and left ventricular stroke index can be calculated. Because a pulmonary artery catheter gives clinicians the ability to measure oxygen delivery directly, it would seem to be an invaluable tool for circulatory monitoring. Unfortunately, routine use of this type of catheter remains controversial. Use of a pulmonary artery catheter has not been shown to decrease patient morbidity or mortality rates. In fact, use of a pulmonary artery catheter may be detrimental. Complications of insertion include pneumothorax, ventricular arrhythmia, ventricular perforation, and pulmonary artery rupture. Until further evidence is published, pulmonary artery catheters should not be used in the ED for assessment and support of the circulatory system.

**BOX 4.3 Arterial Cannulation: Insertion Sites, Possible Complications, Procedure Tips**

**Tips**
- Avoid cannulation of the brachial artery, complications of which can be severe:
  - Forearm ischemia
  - Compartment syndrome
  - Median nerve damage
- A femoral arterial line has a lower rate of catheter malfunction and greater longevity but higher risk for infection.
- Wear a sterile gown, gloves, and mask and place a drape.
- Administer lidocaine without epinephrine for local anesthesia.
- Flush the line frequently to maintain patency and prevent thrombosis.

pulse-contour analysis. As with tissue-specific monitors of hypoperfusion, these noninvasive methods require further prospective analysis before widespread clinical application.

**TREATMENT OF CIRCULATORY DYSFUNCTION**

Treatment goals for circulatory support are based on restoring adequate oxygen delivery. Methods of restoration consist of improving cardiac output, arterial oxygen content, and peripheral perfusion pressure. General ED therapies include supplemental oxygen, endotracheal intubation, intravenous fluids, vasoactive medications, and the use of mechanical support devices such as cardiac pacemakers. Regardless of the therapy chosen, it is important to recognize established end points of circulatory resuscitation. First and foremost, patients should exhibit clinical signs of improvement, such as improving mental status, increasing urine output, and normalization of vital signs. Additional end points of resuscitation are mean arterial blood pressure, serum lactate level, and central venous oxygen saturation. Mean arterial pressure represents true perfusion pressure; its measurement is superior to systolic blood pressure monitoring. Mean arterial pressure in patients with sepsis should be at least 65 mm Hg. There is no survival benefit to raising it beyond that level. As discussed earlier, serum lactate values should show a decreasing trend over serial measurements. Persistently elevated lactate values indicate inadequate and incomplete circulatory resuscitation. For patients with a central venous catheter, CVP and central venous oxygen saturation can be monitored. CVP should range from 8 to 12 mm Hg, whereas central venous oxygen saturation values should exceed 70%. The goals of resuscitation are summarized in Box 4.4.

**GENERAL TREATMENT PRINCIPLES**

Patients with circulatory dysfunction require rapid assessment and simultaneous treatment:

1. Begin cardiac monitoring immediately to determine the patient’s heart rate and rhythm regularity.
2. Provide supplemental oxygen to improve arterial oxygen saturation.

3. Maintain a low threshold for intubation. The respiratory muscles are avid consumers of oxygen, thereby limiting oxygen delivery to other vital organs. Early intubation and paralysis of respiratory muscles may be required in patients with ongoing circulatory compromise.
4. Establish peripheral intravenous access rapidly.
5. Obtain an electrocardiogram and a portable chest radiograph within the first minutes to evaluate for acute myocardial infarction and pneumothorax.
6. Perform ultrasonography early to look for myocardial dysfunction, pericardial effusion, hemoperitoneum, and abdominal aortic aneurysm in patients with persistent hypotension.

**TRENDELENBURG POSITION**

Hypotensive patients are often placed in the Trendelenburg position while resuscitative efforts, such as establishing intravenous access and administering fluids, are initiated. The Trendelenburg position was thought to increase venous return and thereby augment cardiac output. This assumption is incorrect because of the capacitance of the venous circulation. The Trendelenburg position does not promote venous return or increase cardiac output. Hypotensive patients should not be put in the Trendelenburg position. This position serves only to increase the risk for aspiration.

**INTRAVENTOUS FLUID ADMINISTRATION**

Acute circulatory failure should be treated initially with intravenous fluids. In the absence of left ventricular failure, rapid fluid therapy is provided to improve preload and augment cardiac output. For patients without preexisting cardiopulmonary disease, a 20- to 40-mL/kg bolus should be infused over a 10-minute period. In patients with existing cardiac disease, smaller volumes of fluid are infused (e.g., 250 to 500 mL over a 15-minute period). Regardless of the volume chosen, patients must be reassessed after every fluid bolus to determine whether additional treatment is needed.

The administration of colloid fluids during the initial circulatory resuscitation confers no mortality benefit. An isotonic crystalloid solution should be the first-line intravenous fluid. Fluid therapy is continued until the end points of resuscitation are achieved or the patient demonstrates pulmonary edema or evidence of right heart dysfunction.

**Preload Responsiveness**

Before volume resuscitation is initiated in a critically ill patient, preload responsiveness should be assessed; that is, whether cardiac output is likely to improve with the administration of fluids. Depending on the underlying disease, cardiac output might not increase with volume infusion. Additionally, inappropriate administration of volume may be harmful (e.g., exacerbation of pulmonary edema leading to hypoxemia). Several techniques are available for assessment of preload responsiveness.

**STATIC VERSUS DYNAMIC MEASUREMENTS**

Static and dynamic measurements are the two general methods for assessing preload responsiveness. Static measures are used as absolute cutoffs, and examples are CVP and PAOP.

Proponents of the use of CVP to assess preload responsiveness state that blood pressure will probably increase in a hypotensive patient with low CVP when a fluid bolus is given;
that is, the patient will be preload responsive. Conversely, blood pressure will not increase after volume infusion in a hypotensive patient with elevated CVP. These assumptions may be true for hypotensive patients, but the clinical utility of CVP is limited by several factors. CVP is affected by venous compliance, arrhythmias, right-sided heart disease, and alterations in intrathoracic pressure (e.g., as induced by mechanical ventilation). In addition, CVP depends on an appropriately selected reference point, and false results can be obtained if that point is zeroed incorrectly. The same limitations exist when considering PAOP to assess for preload responsiveness, and thus it should be used with caution.

Several studies have demonstrated that static measures are inaccurate in predicting preload responsiveness. Nonetheless, the most recent Surviving Sepsis Campaign consensus guidelines recommend using static measurements such as CVP and PAOP to assess preload responsiveness and guide fluid resuscitation in septic patients.

Given the controversies surrounding the use of CVP for assessment of preload responsiveness, we recommend the following:

- Patients with low CVP who are given a fluid challenge and show at least a 2–mm Hg increase in pressure probably have intravascular depletion and are preload responsive. Such patients require additional fluid administration to optimize preload and cardiac output.
- Normal or elevated CVP should not be interpreted as indicating adequate circulatory volume and cardiac preload. A method other than measurement of CVP should be used to assess preload responsiveness.

Dynamic assessments of preload responsiveness are believed to be more accurate than static assessments. Dynamic measures are derived from the interaction between the respiratory and cardiac systems during mechanical ventilation. Mechanical ventilation elevates intrathoracic pressure, which affects left ventricular preload and changes stroke volume in patients who are preload responsive. Patients who are not preload responsive do not have variations in stroke volume with mechanical ventilation. Stroke volume can be assessed with an arterial catheter or noninvasively by pulse oximeter plethysmographic waveform amplitude.

Dynamic measures predict preload responsiveness as a percentage of change throughout the respiratory cycle. Examples of dynamic measurements for preload responsiveness include stroke volume variation, esophageal Doppler analysis, pulse pressure variation (PPV), the IVC distensibility index (DI), and the passive leg-raise maneuver. Dynamic assessment requires the patient to be mechanically ventilated (except for the passive leg-raise maneuver), to have ventilation at a set tidal volume (6 to 8 mL/kg), to have no spontaneous breaths, and to be in sinus rhythm. The most useful dynamic measures of preload responsiveness for the EP are the DI and PPV.

**DISTENSIBILITY INDEX** The IVC is measured easily and reliably with ultrasound via the subcostal view. In mechanically ventilated patients, variations in intrathoracic pressure cause changes in IVC diameter; that is, increased diameter with a positive pressure breath and decreased diameter with expiration (Fig. 4.10, A and B). This variability in diameter (the DI) is most pronounced when a patient is preload responsive. DI is defined as the difference between the maximum and minimum diameters divided by the minimum diameter × 100. A DI greater than 18% has 90% sensitivity and specificity for predicting preload responsiveness. Because the IVC is easy to visualize and measure, the DI can be assessed following each fluid bolus. By continuously reassessing the DI, volume can be given up to the point at which a patient is no longer preload responsive.

Limitations of the DI include its unreliability in nonintubated patients and uncertainty about the optimal tidal volume and positive end-expiratory pressure during measurements. Nonetheless, because the DI is easy to measure and is reproducible, it remains a clinically valuable tool.

**PULSE PRESSURE VARIATION** PPV is another dynamic measure of preload responsiveness. PPV can be calculated with an arterial catheter or via pulse oximeter plethysmographic waveform analysis. PPV is calculated by taking the percentage of change throughout the respiratory cycle. Examples of dynamic measurements for preload responsiveness include stroke volume variation, esophageal Doppler analysis, pulse pressure variation (PPV), the IVC distensibility index (DI), and the passive leg-raise maneuver. PPV is calculated by taking the difference between the maximum and minimum pulse pressures during one respiratory cycle, dividing by the average of the two values (maximum and minimum), and then multiplying by 100 (Fig. 4.11). Values higher than 18% predict a hypotensive patient to be preload responsive; a volume challenge would probably increase stroke volume and cardiac output.

**Fig. 4.10** Sonographic demonstration of the inferior vena cava in a preload-responsive patient maintained on mechanical ventilation. Notice the variation in diameter between a positive pressure breath (A) and expiration (B).
Vasopressor agents help restore perfusion pressure and maintain cardiac output. These agents typically exert their effects through stimulation of $\alpha$- and $\beta$-adrenergic receptors. The degree to which these receptors are stimulated depends on the agent. Common vasopressor agents used in emergency medicine are norepinephrine, dopamine, and vasopressin. Less commonly used agents are phenylephrine, epinephrine, and milrinone. The hemodynamic dose responses and dosage ranges of these agents are listed in Table 4.5. An important output. 

As mentioned previously, PPV has limitations when used to predict preload responsiveness (e.g., ventilation must be at a set tidal volume [6 to 8 mL/kg], no spontaneous breaths, sinus rhythm).

**VASOACTIVE THERAPY**

Vasoactive medications are indicated when mean arterial pressure remains below 65 mm Hg despite a fluid challenge of 20 to 40 mL/kg and there is evidence that a patient is not preload responsive. Vasopressor agents help restore perfusion pressure and maintain cardiac output. These agents typically exert their effects through stimulation of $\alpha$- and $\beta$-adrenergic receptors. The degree to which these receptors are stimulated depends on the agent. Common vasopressor agents used in emergency medicine are norepinephrine, dopamine, and vasopressin. Less commonly used agents are phenylephrine, epinephrine, and milrinone. The hemodynamic dose responses and dosage ranges of these agents are listed in Table 4.5.
**SUMMARY**

Assessment of the circulatory system is central to the evaluation of every ED patient. Assessment begins with a focused history, physical examination, noninvasive measurements of blood pressure and heart rate, and focused ultrasonography to identify causes of circulatory dysfunction. For many ED patients, additional circulatory assessment and monitoring are not needed. However, patients with evidence of circulatory dysfunction require rapid evaluation and support, as summarized in the following list (Fig. 4.12):

- Obtain peripheral venous access and administer isotonic crystalloid fluid boluses followed by frequent reassessment of blood pressure and preload responsiveness.
- Perform ultrasonography early in the evaluation of patients with severe circulatory compromise to exclude acute life-threatening conditions such as pericardial effusion, hemoperitoneum, and abdominal aortic aneurysm.
- Insert an arterial line for continuous blood pressure monitoring in patients who remain hypotensive despite initial administration of intravenous fluids.

**CHAPTER 4  SHOCK**

Caveat is that a rise in blood pressure after administration of one of these drugs may not correlate with clinical improvement. Additional markers of hypoperfusion, such as the serum lactate level and central venous oxygen saturation, must be considered in the overall circulatory assessment. No studies have clearly supported the superiority of any vasopressor agent. The choice depends on the acute disease process and underlying comorbid conditions.

Patients with poor cardiac contractility may require inotropic support. Inotropic agents increase cardiac contractility through stimulation of $\alpha_1$ receptors, which results in rises in the intracellular calcium concentration. Dobutamine is the prototypic inotropic agent, but any vasopressor that stimulates $\beta_1$ receptors increases cardiac contractility. Dopamine, milrinone, and epinephrine are potent inotropic medications. Dobutamine can also cause peripheral vasodilation in hypovolemic patients. An additional vasopressor medication, such as norepinephrine, should be used in hypotensive patients requiring dobutamine for inotropic support.

**MECHANICAL CIRCULATORY SUPPORT**

Support of the circulatory system may require cardiac pacing (Box 4.5), which can be performed transcutaneously or transvenously. Transcutaneous pacing is noninvasive and more commonly used in the ED. Proper pacer pad placement is crucial in this modality. The anterior pacer pad is placed close to the heart, typically at the location of the V3 lead on an electrocardiogram; the posterior pad is placed between the spine and the inferior border of the left or right scapula. The subsequent steps in transcutaneous pacing are listed in Box 4.6.

Transvenous pacers are placed through a central venous catheter. The right internal jugular vein and the left subclavian vein are the preferred sites of cannulation. Attaining the proper position in the right ventricle can be difficult. Ultrasonography should be used to guide placement of the pacer. If ultrasonography is not available, the V1 lead of an electrocardiograph should be attached to the cathode. Contact with the right ventricle is characterized by prominent ST-segment elevation. The ventricular rate is set the same as for transcutaneous pacing. When pacer output is adjusted, the pacing threshold for transvenous pacing is much less than that required for transcutaneous pacing, typically ranging between 1 and 2 mA. When the right ventricle is paced, the electrocardiogram should demonstrate a pacer spike followed by a QRS complex displaying a left bundle branch block pattern. Potential complications of emergency transvenous pacing are listed in Box 4.7.

**BOX 4.5 Indications for Temporary Cardiac Pacing**

- Witnessed asystole
- Hemodynamically significant bradycardia
- Symptomatic second- or third-degree atrioventricular block
- Complete atrioventricular dissociation with a ventricular rate lower than 50 beats/min
- Termination of supraventricular or ventricular tachyarrhythmias

**BOX 4.6 Steps and Tips for Transcutaneous Pacing**

**Step 1—Set the Rate**
For bradyarrhythmias, set the rate between 60 and 75 beats/min.
For overdrive pacing, set the rate to exceed the rate of the tachyarrhythmia.

**Step 2—Adjust the Output**
The pacing threshold for transcutaneous pacing typically ranges from 20 to 140 mA.
Increase the output (mA) until 100% of beats are captured. Capture is indicated by a spike on the electrocardiogram followed by a wide QRS complex.
Set the output 5 to 10 mA above the threshold value.

**Step 3—Provide Analgesia**
Tip: Patients with emphysema or pericardial effusion or who are mechanically ventilated require higher pacing threshold values.

**BOX 4.7 Complications of Transvenous Pacing**

- Arterial puncture
- Hematoma
- Pneumothorax
- Atrial and ventricular arrhythmias
- Myocardial perforation
- Diaphragmatic stimulation
• Use global markers of hypoperfusion, such as the serum lactate level and central venous oxygen saturation, to detect persistently impaired oxygen delivery.
• Begin a vasopressor agent in any patient with a mean arterial pressure of less than 65 mm Hg despite an adequate fluid challenge.

Emergency Cardiac Ultrasound: Evaluation for Pericardial Effusion and Cardiac Activity

Michael P. Mallin and Christine Butts

KEY POINTS

- Emergency cardiac ultrasound is performed by the emergency physician to assess for the presence of cardiac activity, determine whether a pericardial effusion is present, and answer other specific questions.
- Echocardiography can be used during cardiac arrest to guide resuscitation decisions.
- Emergency use of echocardiography is indicated for assessment of cardiac ejection fraction, wall motion abnormalities, and other critical findings that will direct acute diagnostic decision making.

INTRODUCTION

Echocardiography has been the “gold standard” for cardiologists for decades. Over the past 20 years, emergency physicians have adopted point-of-care (POC) cardiac ultrasound to answer specific questions on the management of critical patients. Assessment for pericardial effusion and for cardiac activity have traditionally been the principal indications for emergency physicians, but indications for bedside echocardiography are growing rapidly.¹

WHAT WE ARE LOOKING FOR

The initial and best evidence-based indications include applications for tamponade, cardiac arrest, and acute heart failure. Rapidly developing areas of cardiac ultrasound include evaluation of hypotension, pulmonary embolism (PE), acute myocardial infarction, diastolic heart failure, and echocardiographically guided resuscitation (Box 5.1).¹²

LITERATURE REVIEW

ESTIMATION OF GLOBAL CARDIAC FUNCTION AND EJECTION FRACTION

Multiple studies have shown the ability of emergency physicians to accurately evaluate cardiac function and ejection fraction.³⁴ When compared with cardiologists, emergency physicians were found to have a correlation coefficient of 0.86 with cardiologists when assessing ejection fraction. Cardiologists had a similar coefficient of 0.84 among themselves.

DIAGNOSIS OF PERICARDIAL EFFUSION

Emergency physicians have proved to be accurate in the diagnosis of pericardial effusion. Previous research has shown that emergency physicians have a sensitivity of 96%⁵ to 100%⁶ as compared with formal overreading by trained echocardiographers.

HOW TO SCAN/SCANNING PROTOCOLS

PROBE SELECTION

Classic echocardiography requires the use of a phased-array probe, sometimes referred to as the thoracic probe. These probes have a small footprint and are ideal for achieving visualization with a small acoustic window between ribs.

ACOUSTIC WINDOWS

Bedside cardiac ultrasound is typically taught with the use of three separate acoustic windows and multiple orthogonal views within the windows. These acoustic windows include the parasternal, apical, and subcostal. Each window is then broken down into orthogonal views, including the parasternal long-axis, parasternal short-axis, apical four-chamber, apical two-chamber, apical long-axis, subcostal four-chamber, and subcostal long-axis views.

PROBE ORIENTATION

Echocardiography places the probe marker on the right side of the ultrasound screen so that when the ultrasound machine is in the cardiac mode, the right-hand side of the screen indicates the side of the probe with the marker on it (this is opposite any other scanning mode).

SPECIFIC VIEWS

Parasternal Long Axis

The parasternal long-axis view seen in Figure 5.1 is obtained by placing the probe in the third to fourth intercostal space with the probe marker pointed toward the patient’s right shoulder (Figs. 5.2 and 5.3). The long axis of the heart should be horizontal on the screen with the apex pointed to the left. If the apex is pointed up, the probe is too low and should be
moved up an interspace. This view allows visualization of the left ventricle, mitral valve, left atrium, right ventricular outflow tract, aortic valve, and aorta. The descending thoracic aorta is often visualized posterior to the left ventricle in transection.

**Parasternal Short Axis**

The parasternal short-axis view is obtained by rotating the probe 90 degrees from the parasternal long-axis position so that the probe marker is pointed to the patient’s left shoulder (Figs. 5.4 and 5.5). The ultrasound beam is now transecting the heart in its short axis. If the physician tilts the probe so that it is pointing to the base of the heart, the aortic valve is visualized along with the “inflow and outflow” of the right heart. This view includes the right atrium, right ventricular outflow tract, and pulmonic valve. As the probe is tilted more apically, the aortic valve is lost and a cross-sectional view of the mitral valve is obtained (Fig. 5.6). At this point the right ventricle becomes more apparent and takes a position as a
crescentic ventricle to the left and superficial to the mitral valve and left ventricle. Finally, as the probe is tilted more toward the apex, the mitral valve is lost and the muscular portion of the left ventricle is visualized. The posterior medial and anterior papillary muscles are visualized at this point, and the circular nature of the left ventricle can be appreciated (Fig. 5.7).

**Apical Four- and Two-Chamber Views**

The apical window allows visualization of either all four chambers (Figs. 5.8 and 5.9) or just two chambers (the left atrium and ventricle) (Fig. 5.10). The apical windows are difficult to obtain in the emergency setting and often require the patient to be in the left lateral decubitus position, which is often impossible. The window is obtained by placing the probe at the location of maximal impulse with the probe marker pointed to the left axilla. The probe must be tilted so that the probe is pointed to the patient’s right shoulder (Fig. 5.11).

The apical two-chamber view allows further evaluation of the left ventricle and mitral valve. The left atrial appendage can sometimes be seen on the right side of the screen on the anterior side of the basal left ventricle.

**Subcostal Four-Chamber View**

The subcostal four-chamber view (Figs. 5.12 to 5.14) is obtained by placing the probe just inferior to the xiphoid and applying pressure downward on the abdomen with the probe.
horizontal. This view can be performed with either the curvilinear abdominal probe or the phased-array thoracic probe. The probe marker should be toward the patient’s left in cardiac mode and toward the patient’s right when using focused abdominal sonography for trauma (FAST) or abdominal protocols.

**NORMAL AND ABNORMAL FINDINGS**

**PERICARDIAL EFFUSION**

Evaluation of pericardial effusion is one of the first indications for cardiac ultrasound. Identification of pericardial effusion (Fig. 5.15) is achieved by visualization of the heart in multiple views. The subcostal window is the most commonly taught site because of the FAST examination. An effusion will appear as an anechoic stripe of fluid surrounding the heart. This stripe is most commonly located between the right ventricle and the liver. Ideally, all three acoustic windows should be used when attempting to rule out pericardial effusion.

The critical complication of pericardial effusion is cardiac tamponade (Fig. 5.16). Physiologically, cardiac tamponade occurs when the pressure inside the pericardial sac becomes elevated above right ventricular diastolic filling pressure. This leads to decreased filling of the right ventricle in diastole and reduced preload and cardiac output. Echocardiographic signs of cardiac tamponade are the presence of right ventricular free wall collapse as seen in Figure 5.16. Alternatively, a more sensitive, but less specific finding is the presence of right atrial collapse during ventricular systole (atrial diastole).

**CARDIAC ARREST**

POC cardiac echocardiography can be invaluable during cardiac arrest. Typical uses include evaluation for tamponade, hypovolemia, and suggestions of PE (clot, right ventricular...
ACUTE HEART FAILURE

Emergency physicians have been shown to be accurate in estimating left ventricular ejection fraction (LVEF). LVEF is most easily separated into three categories: reduced, normal, and hyperdynamic. Although echocardiographers often report actual percentages, we can think of normal LVEF as 55% to 75%, reduced as less than 55%, and hyperdynamic as greater than 75%. Some authors add a fourth category in which severely reduced LVEF is less than 30%. This distinction can be useful when discussing cardiac function with consultants.
The ejection fraction is typically estimated by visual inspection of the “squeeze” of the left ventricle, although it can also be measured with algorithms in the cardiac package of many emergency ultrasound machines.

**Pitfalls**

Emergency cardiac ultrasound involves the use of clear indications and directed ultrasound of the heart to answer specific questions, as described in the “Introduction.” Apart from these questions, a cardiologist should be consulted to aid in complex diagnosis and clinical decision making.

Normal systolic function does not rule out acute heart failure. Diastolic heart failure can occur in patients with a normal LVEF.

Diagnosis of cardiac tamponade by echocardiography can be complicated, and advanced echocardiographic techniques may be required, including Doppler evaluation. Stable patients may benefit from evaluation by a trained echocardiographer.

Technically, the bedside sonographer may encounter difficulty obtaining the full series of views as described earlier. Patient habitus or artifact from the lungs or ribs may present challenges. Placing the patient on the left side in a left lateral decubitus position may aid in better viewing the parasternal and apical windows. This position moves the heart closer to the anterior chest wall. In the subcostal window, asking the patient to breathe in deeply may move the heart closer to the transducer. Additionally, moving the transducer toward the patient’s right, while still pointing toward the left side of the chest, may overcome artifact caused by the stomach or bowel by using the left lobe of the liver as an acoustic window.

**PULMONARY EMBOLISM**

Although cardiac ultrasound cannot identify a pulmonary embolus, several findings are suggestive of this diagnosis. Right ventricular dysfunction and dilation are typically visualized in the apical four-chamber window. Right ventricular dilation has been described in reference to the relative areas of the right and left ventricles at end-diastole. A right-to-left ventricular area ratio of greater than 0.66 has been shown to be 85% specific for PE. Another finding is described as retained apical function in the setting of right ventricular free wall hypokinesis. This is called the McConnell sign and can be fairly specific for PE. McConnell et al. described this particular finding as being 94% specific for PE (Fig. 5.17). An additional finding in acute PE is flattening of the interventricular septum. This is seen in the parasternal short-axis view and is due to either volume or pressure overload of the right heart (Fig. 5.18).

**VOLUME STATUS**

Assessment of the patient’s condition and the presence of hypervolemia or hypovolemia can be complicated. Through direct visualization of chamber size and evaluation of the great vessels, this clinical conundrum can often be overcome.

Echocardiographic evaluation of volume status starts with a global assessment of the ejection fraction and filling of the right and left sides of the heart. Reduced filling of both the right and left heart chambers implies reduced preload and hypovolemia. Conversely, the presence of dilated right and left heart chambers with a poor ejection fraction suggests hypervolemia. Finally, a dilated right ventricle with a contracted left ventricle and an elevated LVEF suggests a forward flow problem of the right heart, such as PE, right-sided myocardial infarction, or cor pulmonale.

Additionally, a body of research has led to evaluation of the inferior vena cava as a surrogate marker for central venous pressure and thus volume status. The current recommendations are summarized in Table 5.1. The inferior vena cava should be measured during both inspiration and expiration from the subcostal long-axis view as seen in Figure 5.19.

Either a two- or single-operator technique is acceptable. A single operator will use the dominant hand to advance and aspirate the needle while manipulating the transducer with the opposite hand. In a two-operator procedure, the cannulating operator will concentrate on the needle and syringe, and the probe will be held steady by the second operator.

Two techniques are commonly accepted for achieving ultrasound-guided vascular access. In the static technique, ultrasound is used to identify vascular structures in relation to external landmarks, and then the ultrasound device is set aside and cannulation performed in the usual manner. The dynamic technique involves real-time, direct visualization of entry of the needle into the vein by ultrasound and seems to be preferable, particularly when the venous structures are small. In this case, once the vein has been accessed (or a “flash” of blood is seen), the ultrasound device is set aside.

The probe most conducive to central venous access is a linear-array high-frequency (5- to 12-MHz) probe (Fig. 6.1). Care should be taken to identify the side of the probe bearing the indicator mark that corresponds to the on-screen indicator. This will allow the most intuitive positioning of the probe during venous access such that medial on the patient is medial on the screen of the machine as viewed by the operator when attempting cannulation (Fig. 6.2).

Once a site has been chosen, usually the internal jugular or femoral, it should be evaluated with ultrasound to identify the artery and the vein (Fig. 6.3). When compared with their accompanying veins, arteries appear thick walled, more circular, and pulsatile on ultrasound. Arteries do not compress with light pressure. Veins are more irregular in shape, sometimes appearing triangular rather than round, and compress with light pressure (see Videos 1 and 2). Use of color Doppler can also aid in identification (see Video 3).

It is often easiest to begin with the probe in a transverse orientation. In this view, the vessels appear in cross section as round or oval structures (see Fig. 6.3). The depth of the target vessel and its relationship to surrounding structures can be determined. The vein should then be centered on the screen. This allows an external landmark, the center of the transducer, to be established. Pressure over this area with a blunt object, such as a fingertip, can confirm the correct location. The needle should then be inserted at a 45-degree angle to the skin.
Video 1  Demonstration of the Valsalva technique for distinguishing the internal jugular (IJ) vein from the carotid artery. When the patient performs a Valsalva maneuver, the IJ is seen to distend slightly, whereas the size of the carotid artery remains constant.

Video 2  Demonstration of the compression technique for distinguishing the femoral vein from the femoral artery. When the skin overlying the vessels is compressed with pressure, the vein is seen to collapse almost fully, whereas the artery deforms only slightly.

Video 3  Video demonstrating the use of color Doppler to identify vessels in the neck. The carotid artery, on the left of the screen, is clearly pulsatile. The internal jugular is seen to the right of the carotid artery.
should be taken to differentiate venous from arterial vessels in this view and to avoid accidental migration of the probe. In this approach the needle should enter the skin at one end of the probe (Fig. 6.7) — and therefore the ultrasound screen — and be advanced in plane toward the underlying vein along the long axis (Fig. 6.8). Similar pressure deformity and indentation of the vessel wall should be noted before it is punctured, and a flash of blood should again be sought (see Video 5).

Video 5 can be found on Expert Consult @ www.expertconsult.com.

An oblique approach has been described in which the vessels are imaged with an orientation in between the
Video 4  Video demonstrating the appearance of the needle tip as it approaches and enters the internal jugular vein in transverse orientation. The needle tip is seen as a hyperechoic (bright white) object moving toward the wall of the vessel.

Video 5  Video demonstrating the appearance of the needle as it approaches and enters the vessel in longitudinal orientation. The needle can be seen in its full length on the left side of the screen advancing toward the vessel.
transverse and longitudinal views. The probe is aligned obliquely over the vessel so that it appears between the structure typically seen in the transverse and longitudinal views. The needle can then be introduced from the end of the transducer and followed in plane as it advances toward the vessel. The oblique approach combines the familiar view of the vessel with the reassurance of being able to view the length of the needle (see Videos 6 and 7).

Videos 6 and 7 can be found on Expert Consult @ www.expertconsult.com.

Ultrasoundography is also commonly used for peripheral approaches to intravenous access, particularly in patients with difficult access, such as those undergoing dialysis or chemotherapy. The basilic vein is usually a good option, even when other peripheral veins are unusable. The extremity chosen should be positioned comfortably and a tourniquet applied to facilitate an initial ultrasound survey to identify candidate veins. The operator localizes the vein and performs cannulation via the transverse or longitudinal approach, as described for central access. Because peripheral veins requiring ultrasound guidance for cannulation are often deeper structures, the use of longer catheters should be considered. It should also be appreciated that peripheral veins are much more likely to collapse with even light pressure from the ultrasound transducer.

Fig. 6.5 Image of a needle tip (seen as the hyperechoic structure on the right of the vessel) entering the internal jugular vein. This image should correspond to a flash of blood seen in the syringe attached to the cannulating needle.

Fig. 6.6 Image of the internal jugular (IJ) and carotid in longitudinal orientation. Note how closely opposed these vessels are to one another. The IJ is the more superficial of the two and has thinner walls. Its size should vary with respiration and compression. The carotid artery is deep to the IJ, has thicker walls, and should not vary in size. At the left of the screen, a catheter or wire is seen within the lumen of the IJ.

Fig. 6.7 Schematic demonstrating the in-plane technique used for longitudinal or oblique placement of a catheter. The indicator in the this image is pointing toward the patient’s feet and the needle is inserted from this end. This causes the needle to appear from the left side of the screen as shown on the right of this figure. It can then be followed in plane as it advances toward the vessel.

Fig. 6.8 Image of a needle advancing toward the internal jugular in longitudinal orientation. The needle is seen on the right of the figure as a hyperechoic object. It can be seen entering the vessel as shown by the arrow.
**Video 6**  Video demonstrating the oblique approach for placement of a central line. In this approach the vessel is seen similar to a transverse image, but the needle is seen on the right side of the image in its full length as it approaches and deforms the vessel.

**Video 7**  Video further demonstrating the oblique approach for central line placement. In this video the needle can be seen within the lumen of the vessel.
Although bedside ultrasound improves the overall success of venous access and decreases complications, it is not without potential pitfalls.

When viewing vessels in the transverse orientation, only a small part of the needle can be visualized. Identifying and following the needle tip immediately after it enters the skin will avoid inadvertent arterial puncture. In the longitudinal orientation, the vein and artery are very closely opposed (see Fig. 6.4). Extra care should be taken to ensure that the vessel on screen is the target vessel.

Both the transverse and longitudinal orientations have limitations in localizing the needle tip. In the transverse orientation, the medial-to-lateral position of the tip can best be determined (Fig. 6.12), but the slope of the needle path may be difficult to appreciate. Conversely, in the longitudinal orientation, the slope can be appreciated, but the medial-to-lateral position may not be apparent (Fig. 6.13). A combination of these two approaches, or the oblique approach, may minimize these potential shortcomings.

It is also important to avoid reliance on any one aspect of the image to identify the structures. Variant vascular anatomy may make landmarks less reliable, and severe volume depletion may lead to a completely collapsed internal jugular vein with a compressible carotid. Multiple characteristics should be examined to confirm that the vessel in question is venous.

Even though visualization of the anatomy does make successful cannulation more likely, it is no guarantee. Inadvertent carotid puncture while using ultrasound guidance is well described, in particular as a result of a through-and-through venous puncture. Prudence and careful technique are always appropriate.
Fig. 6.12 Schematic demonstrating the advantages of transverse orientation for vascular access. In this orientation, the left-to-right (or medial-to-lateral) placement of the needle can be identified. However, the slope of the angle of the needle is out of the plane of this orientation and cannot easily be appreciated. Failure to appreciate this shortcoming may result in inadvertent arterial puncture.

Fig. 6.13 Schematic demonstrating the advantages of longitudinal orientation for vascular access. In this orientation, the slope of the angle of the needle can be identified. However, the right-to-left (or medial-to-lateral) placement of the needle tip cannot easily be appreciated and reduces complications: a randomized, prospective study. Ann Emerg Med 2006;48:540-7.

Management of Cardiac Arrest and Post–Cardiac Arrest Syndrome

William J. Brady, Peter P. Monteleone, Mark Sochor, and Robert E. O’Connor

KEY POINTS

- The ultimate outcome of patients with cardiac arrest is frequently poor but can be improved by immediate bystander cardiopulmonary resuscitation, early defibrillation, and postresuscitation treatment.
- The classic ABC (airway, breathing, circulation) prioritization has changed to CAB to reinforce and prioritize early initiation of high-quality chest compressions and deemphasize early invasive airway management.
- Early defibrillation in patients with ventricular fibrillation and pulseless ventricular tachycardia is aided by various strategies, including automatic external defibrillators and improved provider awareness.
- Interruptions in chest compressions during cardiopulmonary resuscitation should be limited to maximize resuscitation; such interruptions can contribute to an unfavorable outcome.
- Postresuscitation care should include consideration of both induced hypothermia and urgent coronary reperfusion therapy.

EPIDEMIOLOGY

In the United States, sudden cardiac death accounts for approximately 200,000 to 500,000 deaths per year, with nearly half of these events occurring outside the hospital. Regarding the primary inciting event, cardiac causes of sudden cardiac death are most common (Fig. 7.1). Even though individuals with established cardiac disease have a greater than 50% incidence of sudden death, only a minority of cardiac arrest incidents occur in this population. It is estimated that half of all deaths from cardiovascular disease are sudden and unexpected and occur soon after the onset of symptoms. Patient age at the time of cardiac arrest has two distinct peaks—infants younger than 6 months and adults 45 to 75 years of age. Most sudden deaths occur outside the hospital and are often unwitnessed.1,2

Despite comprehensive resuscitation programs and extensive research initiatives, survival rates in most American communities after out-of-hospital cardiac arrest range from 2% to 5%, and survival rates after in-hospital arrest range from 25% to 30%. Despite improvements in prehospital- and hospital-based management strategies and increased awareness in the lay public, cardiac arrest is still associated with extremely high mortality and a dismal neurologic outcome. Immediate, high-quality cardiopulmonary resuscitation (CPR) and effective defibrillation are rarely accomplished quickly enough to increase the likelihood of an improved outcome.

When resuscitation is successful, cardiac dysrhythmias remain a primary concern in the early phase of management of cardiac arrest. The four basic dysrhythmias encountered in cardiac arrest victims include pulseless ventricular tachycardia (VT), ventricular fibrillation (VF), asystole, and pulseless electrical activity (PEA). Pulseless VT and VF result in death unless treated aggressively and rapidly. Asystole, or effective absence of cardiac electrical activity, is the true cardiac arrhythmia (i.e., absence of any rhythm). PEA constitutes a diverse range of rhythms and related clinical scenarios. PEA is an electrical rhythm (i.e., the cardiac rhythm) with absence of discernible mechanical contraction of the heart and no detectable perfusion. The frequency of the dysrhythmias differs depending on the clinical setting (Fig. 7.2).

GENERAL MANAGEMENT CONSIDERATIONS

The core concepts of management of cardiorespiratory arrest include the following goals: reversing any immediately treatable cause and ensuring the basics of circulatory and respiratory support. In the early phases of cardiac arrest, circulation is the most important issue and is addressed by performing high-quality, uninterrupted chest compressions and defibrillation for shockable rhythms.

Resuscitation rates in patients with out-of-hospital and in-hospital cardiac arrest remain poor despite significant advances in the medical sciences. Contemporary research and recommendations have demonstrated that basic life support (BLS) interventions are very important therapies that have a positive impact on outcome.3 This same body of thought and investigation has suggested that advanced life support (ALS) treatments are of less value than originally thought.3 In addition, studies have demonstrated that early access to ALS treatment may be of less importance than previously believed.3,4

In the final phase of the Ontario Prehospital Advanced Life Support trial it was reported that in a community in which
Cardiac arrhythmias encountered in cardiac arrest. 
Emergency physicians should use these protocols and guidelines as important, but they are simply guides to management. Emergency response teams, effective ALS, and coordinated postresuscitation care.5 Only one of these five goals addresses ALS interventions. 

The 2010 guidelines of the American Heart Association (AHA) further deemphasizes advanced interventions. The 2010 AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care list five goals in the approach to cardiac arrest resuscitation: rapid activation of the emergency response team, effective and high-quality chest compressions, early access to defibrillation, effective ALS, and coordinated postresuscitation care.5 Only one of these five goals addresses ALS interventions. 

Critically, both BLS and ALS protocols and guidelines are important, but they are simply guides to management. Emergency physicians should use these protocols and guidelines as a framework to develop and implement the most appropriate management for their patients. 

CPR can be performed in two basic fashions. The traditional, or conventional, method includes chest compressions with ventilations; the newer and probably superior method is termed compression-only CPR and involves chest compressions only with avoidance of early airway management. Each of the management priorities in CPR—circulation, airway, and breathing (CAB)—must be addressed either in sequential fashion (limited personnel available) or simultaneously (multiple personnel available). 

With respect to resuscitation in general and CPR in particular, it is important to note that circulation now precedes airway and breathing. Adequate circulation, largely achieved by appropriate chest compressions with limited interruption and early defibrillation for shockable rhythms, is a necessity throughout the resuscitation event and is particularly important in its early phase. Achieving an adequate airway with appropriate oxygenation and ventilation is an important intervention, but it appears to be less important than early and continuous adequate, uninterrupted chest compressions. Rhythm analysis, pulse determinations, and other periods without chest compression must be minimized so that perfusion can be sustained. 

Numerous investigations have demonstrated that chest compressions are delayed, frequently interrupted, and of poor quality. Wik et al found that CPR was performed only 48% of the time when indicated and that when it was performed, the mean rate was just 64 compressions per minute, with an appropriate depth (at least 5 cm) attained in only 28% of cases. Wang et al. and others reported that CPR was frequently interrupted for prolonged periods, anywhere from 1.8 to 7 minutes, to perform endotracheal intubation.7,8 

One of the key components of the 2010 AHA guidelines5 is the change from performing the ABCs (airway, breathing, circulation) to the CABs,9 thus demonstrating how important compressions are relative to airway management and oxygenation—particularly early in cardiac arrest. Chest compression-only CPR has been proposed as an alternative method of basic resuscitation that is superior to traditional CPR with chest compressions and ventilations. The basic component of compression-only CPR is the performance of continuous, uninterrupted chest compressions of high quality. Compression-only CPR suggests that early management of the airway is not a priority. 

Compression-only CPR has been shown to have similar efficacy to conventional CPR in terms of neurologically intact survival at 1 year in victims of witnessed cardiac arrest.10 In patients with an initially shockable rhythm, Kellum et al. demonstrated an increased survival rate with neurologically intact status after receiving compression-only CPR.11 The SOS-KANTO (Survey of Survivors After out-of-Hospital Cardiac Arrest in the Kanto Area of Japan) trial reviewed 4068 patients with witnessed out-of-hospital cardiac arrests, 1151 of whom received bystander CPR. The 439 subjects who received hands-only CPR showed similar neurologic outcome at 30 days as did those who received conventional CPR (6% versus 4% of survivors); no benefit was seen with the addition of mouth-to-mouth ventilation.12 In 2008 using the concept of minimally interrupted cardiac resuscitation, Bobrow et al.
demonstrated that cycles of 200 continuous compressions, followed by electrical defibrillation with immediate resumption of compressions before endotracheal intubation, resulted in an increased survival rate (1.8% versus 5.4%) in all patients. In the witnessed VF subgroup, the survival rate increased from 4.7% to 17.6%.13

When performing CPR, early emphasis on the airway and breathing components of CPR can hinder appropriate chest compressions and produce excessive ventilations. The concept of death by hyperventilation is based on overdistension of the thoracic cavity, which results in increased intrathoracic pressure. Increased intrathoracic pressure can impede venous return to the right side of the heart. Reduced venous return limits preload of the left ventricle, thereby resulting in diminished cardiac, cerebral, and vital organ perfusion. Excessive ventilation rates must be avoided; a ventilatory rate of 8 to 10 breaths/min is appropriate via either bag-mask ventilations or endotracheal tube.

**ELECTRICAL THERAPY**

Electrical therapy—defibrillation and transectaneous cardiac pacing—can be lifesaving when used in an appropriate and timely fashion. Early defibrillation improves survival rates, but only if accomplished within minutes. This therapy is appropriate only for pulseless VT and VF, and it has no indication in managing asystole or PEA rhythms.

Defibrillators exist in two basic styles—monophasic and biphasic. Most commercially available defibrillators (automatic and manual) are biphasic, although many monophasic models remain in use today. No defibrillator style, monophasic or biphasic, is associated with unequivocally higher rates of successful resuscitation or survival to hospital discharge. The biphasic defibrillator has achieved a higher rate of termination of pulseless VT and VF, but this early benefit has not translated into survival to hospital discharge with meaningful quality of life. When using a monophasic defibrillator, a 360-J shock should be applied; if a biphasic unit is in operation, the equivalent, device-specific maximal emergency should be applied. In either type of device, a single shock is delivered initially and in subsequent defibrillations.

Use of an automated external defibrillator (AED) is a lifesaving intervention when applied appropriately. Use of an AED by trained lay rescuers (the Public Access Defibrillation [PAD] program) has resulted in a markedly shorter time to defibrillation and an improved rate of resuscitation. AED use by nontrained rescuers in a PAD application has anecdotaly demonstrated positive outcomes, but its use by untrained personnel requires additional investigation. The Targeted First Responder (TFR) application has also demonstrated significant success.

No conclusive data are available on the ideal timing of the initial defibrillation, regardless of the downtime. The AHA recommendation states that a patient in cardiac arrest with a shockable rhythm should undergo electrical defibrillation as soon as possible. Chest compressions should be initiated as soon as the defibrillator is located, applied, and activated.

The most recent analysis of the timing of initial defibrillation suggests that there is no benefit with delayed defibrillation, even in patients with prolonged downtimes. Simpson et al. performed a meta-analysis of the existing literature and noted that no benefit was found in delaying the first shock in patients with prolonged downtimes or unwitnessed arrest (or both).14 The cumulative data demonstrated no benefit in providing chest compression before defibrillation versus immediate defibrillation and also no harm in performing CPR before the initial defibrillation. The 2010 AHA guidelines also acknowledged that the literature does not support a chest compression–first approach, thus suggesting that clinicians should provide both therapies (chest compression and defibrillation) and base the time of the first defibrillation on analysis of the setting, personnel, and equipment parameters for individual cases.

The other primary form of electrical therapy used in managing cardiac arrest is transcutaneous cardiac pacing. Very early use of transectaneous ventricular pacing can be considered, although conclusive supporting evidence is lacking. Transcutaneous pacing is much less effective after the loss of spontaneous circulation or prolonged cardiac arrest.15,16 Transcutaneous pacing is a rapid, minimally invasive means of treating asystole and PEA bradyarrhythmias. Transcutaneous pacing electrodes are applied to the skin of the anterior and posterior chest walls, and pacing is initiated with a portable pulse generator. In an emergency situation, this type of pacing technique is easily and rapidly accomplished when compared with other methods of cardiac pacing.

**PHARMACOLOGIC THERAPY**

Although numerous medications may be used in a resuscitative event, several “code drugs” are of potential importance, including epinephrine, vasopressin, atropine, amiodarone, lidocaine, magnesium, calcium, and sodium bicarbonate. Research into resuscitation after cardiac arrest has demonstrated that BLS interventions significantly contribute to favorable outcomes and that ALS treatments are less valuable than originally thought.2,17 A review of the issue has suggested that the use of cardioactive medications can increase the rate of successful resuscitation but does not alter the ultimate survival rate or have an impact on neurologic status at discharge among survivors.18

Because these code drugs are still used with significant frequency by clinicians during resuscitation of patients in cardiac arrest, an understanding of these medications and their potential impact is essential. The code drugs are separated into several subcategories, including vasopressors (epinephrine and vasopressin), parasympatholytic drugs (atropine), antiarrhythmic agents (lidocaine and amiodarone), electrolytes (calcium and magnesium), buffer (sodium bicarbonate), and fibrinolytic medications.

The two primary vasopressor agents used in resuscitation are epinephrine and vasopressin. Epinephrine and vasopressin have demonstrated increased rates of return of spontaneous circulation (ROSC) but have not produced meaningful increases in survival to hospital discharge with intact neurologic status. Both vasopressors are indicated in all three cardiac arrest treatment scenarios, including pulseless VT and VF, PEA, and asystole. These medications can be used interchangeably in the cardiac arrest scenario; that is, use of one type of vasopressor does not preclude future use of the other agent in that same resuscitation. The vasopressor class of resuscitative agents does not preclude the use of other agents, including vasopressin; however, the vasopressor is not used in conjunction with other agents.
Atropine is a parasympatholytic drug that enhances both sinoatrial node automaticity and atrioventricular conduction via direct vagolytic action. In cardiac arrest, atropine can be considered in patients with both asystole and PEA, particularly those with bradydysrhythmic electrical activity. It is important to note that the AHA has removed atropine from all cardiac arrest algorithms.5,9 Removal of atropine is based not on any negative impact on patient outcome but on a significant lack of benefit.5,9 Atropine is still recommended in patients with compromising bradydysrhythmia with intact perfusion.5,9,19,20

Amiodarone and lidocaine are the primary antidysrhythmic agents used in cardiac arrest resuscitation scenarios. Amiodarone has a very broad range of mechanisms, including sodium and calcium blockade, antagonism of potassium efflux, and adrenergic blocking effects. In cardiac arrest, indications for its use include pulseless VT and VF unresponsive to CPR, defibrillation, and an initial vasopressor. Although amiodarone has demonstrated impressive results in terms of ROSC after cardiac arrest, it has not altered the ultimate outcome—meaningful survival to hospital discharge. Lidocaine is a well-known and widely used antidysrhythmic agent with limited efficacy in cardiac arrest. Unfortunately, lidocaine has demonstrated no alteration in outcomes of patients with out-of-hospital cardiac arrest secondary to pulseless VT and VF. Furthermore, when compared with amiodarone, lidocaine has been shown to have a less favorable rate of ROSC and an increased rate of asystole in general and following defibrillation. Like amiodarone, it may be used in patients with pulseless VT and VF unresponsive to initial therapies. At the present time, lidocaine is best considered an alternative to amiodarone for refractory pulseless VT and VF.

The electrolytes magnesium and calcium play a limited role in resuscitation. Magnesium should be used in patients with polymorphic VT (PVT) thought to be torsades de pointes (TdP). Possible secondary indications for magnesium include PEA cardiac arrest potentially resulting from hyperkalemia and cardiorespiratory arrest related to toxemia of pregnancy. Use of calcium should be limited to cardiac arrest involving excessive parenteral magnesium administration, hyperkalemia, and cardiotoxin ingestion.

Sodium bicarbonate is a potent buffer, but no evidence supports its widespread use for cardiac arrest. Sodium bicarbonate can adversely affect perfusion in certain vascular beds, unfavorably alter acid-base status at the tissue and cellular levels, and promote hyperosmolarity and hypernatremia. Sodium bicarbonate has several specific clinical scenarios in which it is potentially indicated: tricyclic antidepressant overdose (and other sodium channel blocking agents), severe acidosis (metabolic and respiratory), hyperkalemia, and prolonged cardiac arrest.

Acute thrombosis with or without embolization, either coronary or pulmonary, can cause cardiac arrest. Many investigators have considered the early use of fibrinolytic agents in the management of cardiac arrest with known or presumed acute thrombosis. Anecdotal reports describe the cases of adult patients who have been successfully resuscitated following the administration of a fibrinolytic agent when the condition leading to the arrest was acute myocardial infarction (AMI) or acute pulmonary embolism.21 The 2010 AHA guidelines state that the evidence is insufficient to advocate the routine use of fibrinolytic agents during cardiac arrest but that its use should be considered on a case-by-case basis. Fibrinolytic agents are a level IIb recommendation in cardiac arrest secondary to pulmonary embolism.5,9

THE AIRWAY
The AHA has moved away from the airway-first strategy with a reordering of the resuscitation alphabet from the ABCs to the CABs, thus highlighting the relative importance of circulation over airway management.5,9 This change in strategy is based on the relative importance of circulation but also on the fact that airway interventions, particularly placement of an invasive airway, can interrupt continuous chest compressions and lessen the central nervous system (CNS), cardiac, and systemic perfusion produced by CPR. The airway should be managed invasively once appropriate chest compressions have been initiated and sustained and defibrillation has taken place. Management of the airway must not hinder appropriate chest compressions and other basic interventions. In cardiac arrest scenarios caused by a compromised airway or inadequate oxygenation and ventilation, or both, attention to invasive management of the airway is important.

MANAGEMENT OF SPECIFIC DYSRHYTHMIAS

VENTRICULAR FIBRILLATION AND PULSELESS VENTRICULAR TACHYCARDIA
VF and pulseless VT are discussed together because they occur in the same clinical settings and have similar mechanisms, causes, and modes of therapy. The only clinically significant classification system of VF concerns the amplitude of the chaotic waveform deflections. Regardless of the morphology of VF, without prompt therapy, VF invariably results in death.

VF is divided into two clinical types. It is considered primary in the absence of acute left ventricular dysfunction and cardiogenic shock, and it is noted in approximately 5% of patients with AMI. The majority of primary VF episodes occur within the first 4 hours of AMI, and 80% are seen within the initial 12-hour period of infarction. VF may represent abrupt reperfusion, but recurrent or ongoing ischemia is more likely. The overall prognosis for patients with primary VF does not differ from that in AMI patients without VF after a brief period of increased inpatient mortality. Secondary VF can occur at any time in the course of AMI; may be complicated by acute heart failure, cardiogenic shock, or both; and occurs in up to 7% of patients with AMI. Unlike primary VF, the prognosis for patients with secondary VF is poor, with in-hospital mortality approaching 60%, and long-term mortality beyond 5 years remains poor.

In contrast to VF, VT usually originates from a specific focus in the ventricular myocardium or in the infranodal conduction pathway. VT is defined as a rapid, wide regular QRS complex tachycardia originating from infranodal cardiac tissue. VT can be classified from several different perspectives, including the overall clinical findings (stable versus unstable), the hemodynamic state (presence or absence of a pulse), its temporal course (sustained versus nonsustained), and its morphology (monomorphic versus polymorphic). In sudden cardiac death, it is most appropriate to consider VT...
from the perspective of the overall clinical findings, with an emphasis on the temporal and hemodynamic factors. In this instance, VT is considered pulseless and sustained and thus unstable. Pulseless VT accounts for a minority of the rhythms seen in cardiac arrest and has the most favorable prognosis. This relatively infrequent occurrence results from an early appearance with rapid degeneration. If therapy is not initiated in arrest events, this rhythm rapidly decompensates into more malignant rhythms such as VF or asystole.

Pathophysiology
These malignant dysrhythmias most often arise as a result of direct myocardial damage (i.e., AMI, myocarditis, cardiomyopathy), medication toxicity, or electrolyte abnormality. The pathophysiology usually involves either a reentry phenomenon or triggered automaticity. A reentry circuit within the ventricular myocardium is the most common source. The properties of a reentry circuit involve two pathways of conduction with differing electrical characteristics. The reentry circuits that provide the substrate for VT and VF generally occur in a zone of acute ischemia or chronic scarring. This dysrhythmia is usually initiated by an ectopic beat, although a number of other factors can be the primary initiating event, including acute coronary ischemia, electrolyte disorders, and dysautonomia. Triggered automaticity of a group of cells can result from various cardiac anomalies, including congenital heart disease, acquired heart ailments, electrolyte disorders, and medication toxicity.

One electrophysiologic model describes these ventricular dysrhythmias with respect to morphology and suggests that the three entities (VF, PVT, and monophasic VT [MVT]) are manifested across an electrophysiologic spectrum. This model notes that PVT differs from VF and MVT in frequency, amplitude, and variability, thus suggesting that MVT, PVT, and VF are states of electrical activity occurring across a spectrum of ventricular dysrhythmia. In this model, MVT is the most highly organized rhythm, whereas VF is the least; PVT represents an intermediate entity between the two end points of the spectrum.

Clinical Presentation
VENTRICULAR FIBRILLATION
VF results in a lack of spontaneous perfusion except in the rare case of a witnessed, recent onset in which the patient is able to cough, thereby enabling perfusion to continue for a short period. VF is diagnosed electrocardiographically (Fig. 7.3) in pulseless and apneic patients by the presence of lower amplitude and chaotic activity. The rate of the deflections is usually between 200 and 500 depolarizations per minute. Morphologically, VF is divided into coarse (Fig. 7.3, A) and fine (Fig. 7.3, B and C). Coarse VF tends to occur early after cardiac arrest; is characterized by high-amplitude, or coarse, waveforms; and has a better prognosis than fine VF does. With continued cardiac arrest the amplitude dampens, with a less dramatic appearance of the dysrhythmia and fine VF (Fig. 7.3, B and C) ultimately being produced. The R-on-T phenomenon can result in VF as noted in Figure 7.3, D and E.

Fine VF may be confused with asystole. If the sensing electrode is oriented perpendicular to the primary depolarization vector, the amplitude of the deflections is minimal, thus mimicking asystole. Such mimicking can have a negative impact on patient care if electrical defibrillation is not considered. This potential pitfall can easily be avoided if the dysrhythmia is viewed in at least two or three simultaneous or consecutive electrocardiographic leads. Fine VF has a significantly greater incidence of post-countershock asystole than coarse VF does. In this instance, aggressive resuscitation will probably improve the hemodynamic state and increase the opportunity for ROSC.

VENTRICULAR TACHYCARDIA
VT is defined as three or more ventricular beats in succession with a QRS complex duration of greater than 0.12 second and a ventricular rate greater than 100 or 120 beats/min (Fig. 7.4). Most instances of VT are characterized by very rapid rates; however, patients may have slower versions of VT, particularly if using amiodarone.

From an electrocardiographic perspective (Fig. 7.5; also see Fig. 7.4), the morphology of the VT is of importance. MVT (Fig. 7.5, A and B) is identified when each consecutive waveform has a single morphology; that is, the beat-to-beat variation in QRS complex morphology is negligible. The rate is usually between 140 and 180 beats/min and very regular. MVT is the most common form of VT and is seen in 65% to 75% of patients with VT in the out-of-hospital setting (Fig. 7.6). In patients with MVT, the cause of the dysrhythmia is usually myocardial scarring from a previous infarct.

PVT (see Fig. 7.4) is characterized by a frequently changing QRS complex (see Fig. 7-5, C and D). The QRS complex tends to be greater than 0.12 second with beat-to-beat variations in morphology and width. Significant variability in the R-R interval and QRS complex axis is present. Its rate is usually more rapid than that of MVT, with a range of 150 to 300 beats/min, and PVT accounts for 25% to 30% of cases of VT in patients with out-of-hospital cardiac arrest (see Fig. 7.6).

The PVT subtype TdP (see Fig. 7.4) demonstrates polymorphic QRS complexes that vary from beat to beat (Fig. 7.7, A and B; also see Fig. 7.5, D). The variation is often quite pronounced and easily observed. TdP has a highly characteristic electrocardiographic pattern; the literal translation of the French term torsades de pointes—“twisting of the points”—elegantly describes the appearance of the QRS complex as it varies in amplitude and appears to rotate about the isoelectric baseline in a semisinusoidal fashion. Also required for electrocardiographic (and clinical) diagnosis of TdP is demonstration of abnormal repolarization as manifested by prolongation of the QT interval on the electrocardiogram when the patient is in a supraventricular rhythm (either before or after cardiac arrest) (Fig. 7.7, B).

Management of Pulseless Ventricular Tachycardia and Ventricular Fibrillation
Resuscitative management of these two malignant dysrhythmias is similar. The basic approach (Table 7.1) includes CPR, with an emphasis on high-quality chest compressions, and electrical defibrillation. Once defibrillation has occurred, CPR is resumed for an additional 2 minutes. If the dysrhythmia persists on electrocardiographic analysis, a vasopressor is administered, either vasopressin or epinephrine. Epinephrine should be used in 1-mg doses, preferably administered via an intravenous or intraosseous line. If given by endotracheal tube
Fig. 7.3 Ventricular fibrillation. A, Coarse ventricular fibrillation. Note the large-amplitude deflections with no organized electrical activity. B, Ventricular fibrillation with low to intermediate deflections in amplitude; also, the absence of organized electrical activity is obvious. C, Very fine ventricular fibrillation. Note the apparent absence in this lead (lead II) of deflection. This rhythm may be incorrectly diagnosed as asystole if the patient is monitored solely with a single electrocardiographic lead. D, Sinus tachycardia with degeneration into ventricular fibrillation. Note the appearance of the R-on-T phenomenon, with the R wave of an early beat falling on the T wave of the preceding beat. The repolarization period of the electrocardiographic cycle is an electrically vulnerable period of the cardiac phase—insults, such as subsequent depolarizations, may cause the development of ventricular tachycardia or ventricular fibrillation. In this case, the patient has a short period of polymorphic ventricular tachycardia followed by coarse ventricular fibrillation. E, R-on-T phenomenon with the R wave (thin arrow) of an early beat falling on the T wave (thick arrow) of the preceding beat, followed by a short period of polymorphic ventricular tachycardia.
Fig. 7.4 Morphologic description of ventricular tachycardia (VT). Morphologically, VT can be divided into monomorphic and polymorphic based on the nature of the QRS complex. Polymorphic VT (PVT) can be further subdivided into torsades de pointes (TdP) PVT and non-TdP PVT—this distinction considers not only the morphology of the QRS complex but also other electrophysiologic issues (the repolarization state as manifested by the QT interval); with TdP PVT, prolongation of the QT interval is noted—this determination obviously can only be made when the patient has an electrocardiogram exhibiting a supraventricular rhythm.

Fig. 7.5 Ventricular tachycardia. A, Monomorphic ventricular tachycardia. Note the very wide QRS complex and rate of approximately 150 beats/min. B, Monomorphic ventricular tachycardia. Note the very rapid rate of approximately 240 beats/min. C, Polymorphic ventricular tachycardia (PVT). The QRS complex is continually changing (potentially both in amplitude and morphology) in any single lead. The QRS complex also tends to be greater than 0.12 second with beat-to-beat variations in morphology and width being encountered; significant variability in the R-R interval and QRS complex axis is noted as well. D, PVT, torsades de pointes (TdP) type. Note the marked, beat-to-beat variation in QRS complex morphology occurring in a gradual pattern. The QRS complex ranges from small to large with an undulating pattern, as though it is “twisting about a point”—the TdP version of PVT. TdP PVT has a characteristic appearance—the QRS complex varies in amplitude and appears to rotate about the isoelectric baseline in a semisinusoidal fashion. Also required for the electrocardiographic (and clinical) diagnosis of TdP is demonstration of abnormal repolarization manifested by prolongation of the QT interval on the electrocardiogram when the patient is in a supraventricular rhythm.

VT MORPHOLOGY TYPE
Prehospital cardiac arrest population

Fig. 7.6 Morphologic subtypes of ventricular tachycardia (VT) in prehospital cardiac arrest patients. In patients with polymorphic VT (PVT), both non–torsades de pointes (Non-TdP) and TdP versions are seen in approximately equal frequency. MVT, Monophasic ventricular tachycardia.
Fig. 7.7  A, Torsades de pointes (TdP) polymorphic ventricular tachycardia. The appearance of the QRS complex is characteristic of this subtype of polymorphic ventricular tachycardia—in any single electrocardiographic lead it varies in both morphology and amplitude and appears to rotate about the isoelectric baseline in a semisinusoidal fashion. B, TdP polymorphic ventricular tachycardia. Note the polymorphous QRS complexes that vary from beat to beat. The variation is often quite pronounced, with marked variation easily observed in any single lead from one beat to the subsequent beat. TdP also demonstrates a highly characteristic electrocardiographic pattern; the literal translation of the French term torsades de pointes—“twisting of the points”—elegantly describes the appearance of the QRS complex as it varies in amplitude and appears to rotate about the isoelectric baseline in a semisinusoidal fashion. Also required for diagnosis is demonstration of abnormal repolarization as manifested by prolongation of the QT interval on the electrocardiogram when the patient is in a supraventricular rhythm (i.e., before arrest or after successful resuscitation and return of spontaneous circulation).
A larger dose of two to three times the intravenous dose is recommended. Dosing through the ETT is not currently considered to be the most effective means of delivering the medication. Epinephrine should be readministered every 3 to 5 minutes during the resuscitation. In certain situations such as ingestion of a cardiotoxic drug, higher doses of epinephrine may be required, but this issue has not been explored. Vasopressin is administered via the intravenous or intraosseous routes at a dose of 40 international units (IU). In multiple studies of vasopressin alone or vasopressin versus epinephrine in prehospital and hospital-based populations, no significant difference has been found in survival to hospital discharge.\textsuperscript{24-26}

A single dose of vasopressin may be used as either the first or second vasopressor administered, and epinephrine can be used in a primary or secondary role.

After the administration of a vasopressor, CPR should be continued for 2 minutes, followed by a second defibrillation. If the VT or VF persists, amiodarone or lidocaine should be administered. Amiodarone is the preferred agent and should be considered in patients with pulseless VT or VF that is unresponsive to CPR, a vasopressor, and defibrillation. It is administered to a pulseless patient in a bolus dose of 300 mg intravenously, and it can be repeated with a second dose of 150 mg intravenously. Amiodarone has demonstrated a benefit over both placebo and lidocaine in this patient group. Even though rates of ROSC and survival to hospital admission were greater in amiodarone-treated patients, ultimate survival to hospital discharge was no different.\textsuperscript{27,28}

PVT should be managed in similar fashion to pulseless MVT or VF. CPR, defibrillation, a vasopressor, and antidysrhythmic agents are appropriate therapeutic interventions. In two comparisons of MVT and PVT in prehospital patients with cardiorespiratory arrest, MVT occurred (60\%) more often than PVT (15\%) and TdP (15\%).\textsuperscript{22,23} Clinical outcomes were similar in both rhythm groups with similar therapies. Patients with the subset of TdP also fared as well as the non-TdP PVT and MVT groups.\textsuperscript{22,23} If sustained, PVT is often than PVT (15\%) and TdP (15\%).\textsuperscript{22,23} Clinical outcomes were similar in both rhythm groups with similar therapies. Patients with the subset of TdP also fared as well as the non-TdP PVT and MVT groups.\textsuperscript{22,23} If sustained, PVT is often than PVT (15\%) and TdP (15\%).\textsuperscript{22,23} Clinical outcomes were similar in both rhythm groups with similar therapies. Patients with the subset of TdP also fared as well as the non-TdP PVT and MVT groups.\textsuperscript{22,23} If sustained, PVT is
PULSELESS ELECTRICAL ACTIVITY

Definition
PEA is indicative of a very serious underlying medical event, such as profound hypovolemia, massive myocardial infarction, large pulmonary embolism, significant electrolyte disorder, or cardiotoxic overdose. PEA features the unique combination of no discernible cardiac mechanical activity (i.e., a pulseless state) with persistent cardiac electrical activity (i.e., the cardiac rhythm). Essentially, any dysrhythmia other than VT or VF may be seen (Figs. 7.8 and 7.9).

Pathophysiology
PEA must be separated into pseudo and true subtypes. Pseudo-PEA occurs when cardiac electrical activity (i.e., a cardiac rhythm) is present but a palpable pulse is absent and myocardial contractions are demonstrated by echocardiography or some other imaging modality. In true PEA, cardiac electrical activity in the form of a rhythm is noted, but absolutely no mechanical contraction of the heart is occurring.

It is important to distinguish the two subtypes of PEA. With pseudo-PEA, a significant pathophysiologic event has impaired the cardiovascular system’s ability to perfuse. These cases usually involve profound hypovolemia as a result of hemorrhage, obstruction to forward flow secondary to massive pulmonary embolism, tension pneumothorax, or cardiac tamponade; hypocontractile states with poor vascular tone such as advanced anaphylactic or septic shock; or very rapid
tachydysrhythmia. Rhythms in these situations usually include tachycardias, predominantly sinus tachycardia or atrial fibrillation with rapid ventricular response. A directed therapeutic approach coupled with aggressive resuscitation will provide patients with pseudo-PEA with the best chance for survival.

True PEA occurs with primary electromechanical uncoupling of myocytes. From a cardiac electrical perspective, this uncoupling event is usually characterized by abnormal automaticity and disrupted cardiac conduction that results in the continued presence of a cardiac rhythm. Mechanically, this uncoupling is probably due to global myocardial energy depletion. Local myocardial tissue issues (hypoxia, acidosis, hyperkalemia, and ischemia) also contribute to this electromechanical dissociation. True electromechanical dissociation is seen in patients with prolonged cardiac arrest states, including metabolic, hypothermic, and poisoning sudden death scenarios. Another important subgroup of true PEA is characterized by patients with prolonged VF who are defibrillated to an electromechanical dissociation state with a broad QRS complex, bradycardic rhythm. In this instance, nearly complete exhaustion of energy substrate associated with profound hypoxia and acidosis accounts for this dismal scenario.

The PEA event usually starts with impaired perfusion and progresses to pseudo-PEA with continued cardiac contractions. Absence of a discernible pulse followed by loss of cardiac mechanical activity yields the development of true PEA.

**Clinical Presentation**

Causes of PEA are numerous (see Table 7.1), spanning all of acute care medicine, and include profound hypovolemia, cardiac tamponade, large anterior wall myocardial infarction, tension pneumothorax, massive pulmonary embolism, severe sepsis, anaphylactic reaction with shock, significant electrolyte abnormality (e.g., disorders of potassium), pronounced metabolic acidosis, substantial cardiotoxic ingestion, and hypothermia. These conditions have a final common pathophysiologic denominator of severe hypovolemia (absolute or relative), marked obstruction to flow, profound hypocontractility, or any combination of the three. The PEA rhythm manifestations are numerous. The most frequent dysrhythmias seen in PEA include idioventricular, junctional, and sinus bradycardia (see Figs. 7.8 and 7.9). Some causes of PEA are reversible if recognized early and treated correctly in the initial phases of resuscitation. Hemorrhagic shock, pulmonary embolism, pericardial effusion, and tension pneumothorax can all lead to PEA and are potentially reversible.

The electrocardiographic rhythm may be a useful guide to the etiology and a key to successful resuscitation. Rapid, narrow–QRS complex tachycardic manifestations are associated with a somewhat better opportunity for survival. Profound hypovolemia is the most frequently encountered event in patients with PEA. In an attempt to maintain cardiac output, the heart will increase its rate. This increased rate will usually be in the form of sinus tachycardia. In patients with atrial fibrillation, a rapid ventricular response will be present and create a manifestation that is probably a pseudo-PEA cardiac arrest.

Only 2% to 3% of patients with PEA as the initial or primary dysrhythmia in cardiac arrest survive to hospital discharge neurologically intact. Electrocardiographic variables may be predictive of successful resuscitation. Rapid rhythm rates are much more frequently associated with ROSC than sinus bradycardia is. The width of the QRS complex is also potentially predictive of resuscitative outcome. Progressively wider QRS complexes are found in patients with a lower likelihood of restoration of spontaneous perfusion. In this risk prognostication application, an idioventricular rhythm is associated with a lower chance of resuscitation than is sinus bradycardia with a normal QRS complex duration. Other electrocardiographic findings encountered in PEA patients successfully resuscitated include the development of P waves and shortened QT intervals.

**Management**

Management of a patient in PEA arrest should focus on standard resuscitation treatments and rapid identification and correction of reversible causes, but it is otherwise similar to the treatment of pulseless VT and VF (Table 7.2).

In the 2010 AHA guidelines, atropine was removed from the PEA and asystole algorithm. Atropine was removed not because of any harm induced but because of lack of efficacy. The clinician at the bedside should use clinical judgment to determine whether atropine should be administered in this rhythm scenario. Epinephrine is recommended at a dose of 1 mg intravenously, repeated every 3 to 5 minutes during resuscitation. Vasopressin, 40 IU intravenously, can also be used once in the resuscitation event. Aggressive volume replacement with either crystalloid or colloid is recommended. Attention to the various causes and focused treatment of PEA is encouraged early in the resuscitation (see Table 7.1).

**ASYSTOLE**

**Definition**

Asystole is the absence of any heart and all cardiac electrical activity and usually results from failure of impulse formation in the primary (sinoatrial node) and default (atrioventricular node and ventricular myocardium) pacemaker sites. Asystole can also result from failure of propagation of impulses to the ventricular myocardium from atrial tissues.

**Pathophysiology**

Patients with asystole have generally experienced prolonged cardiac arrest, probably initially manifested by either VT, VF, or PEA and ultimately degenerating to complete cessation of cardiac electrical activity. Asystole can be structurally mediated as a result of large myocardial infarction, neurally mediated as seen in aortic stenosis, or functionally mediated by cardiotoxic ingestion or metabolic poisoning. Regardless of the clinical event or mechanism responsible, patients with asystole demonstrate complete exhaustion of myocardial energy stores.

**Clinical Presentation**

The AHA in the advanced cardiac life support (ACLS) teaching describes refractory asystole as “…the transition from life to death.” These patients have probably been in full cardiorespiratory arrest for prolonged periods. Patients with asystole as the initial or primary dysrhythmia most often do not survive. At best, 1% to 2% of patients with presumed asystole as the initial or primary dysrhythmia in cardiac arrest survive to hospital discharge and have a meaningful quality of life after arrest.
In asystole, the electrocardiogram demonstrates a flat line or nearly flat line (Fig. 7.10). Minimal undulations of the waveform resulting from electrocardiographic baseline drift can be seen. Several pitfalls must be avoided in the apparent asystolic manifestation, including monitor malfunction, disconnection of electrocardiographic leads, and fine VF with minimal amplitude in the imaging lead. The last potential error can be detected by confirming asystole with at least two leads oriented in perpendicular fashion (see Fig. 7.10).

**Management**

Resuscitation should follow a similar algorithm as that for PEA (Table 7.3), with the notable exception of consideration of cardiac pacing. Even though several trials have not demonstrated a benefit of transthoracic pacing in patients with asystolic arrest, it is not unreasonable to consider a short course of cardiac pacing if performed very early in the resuscitation. A comment should be made on the choice of vasopressor. One large study demonstrated a short-term survival benefit of vasopressin with respect to epinephrine in these patients, and this benefit remained apparent at hospital discharge.26

**SPECIAL ARREST POPULATIONS AND SCENARIOS**

**Traumatic Injury**

Multiple traumatic causes can lead to cardiac arrest. The prognosis of patients with out-of-hospital cardiac arrest as a result of trauma is poor, particularly in the setting of blunt injury.31

In cases of traumatic arrest in which a clear etiology is not readily apparent, aggressive resuscitation is indicated, although the prognosis is bleak. General trauma management...
should be performed while specific therapy is aimed at the medical portion of the cardiorespiratory arrest. Standard ALS interventions aimed at management of the dysrhythmia should be pursued with the realization that the likelihood of successful resuscitation is minimal. Pulseless VT and VF should be defibrillated immediately on recognition. In most traumatic situations, the underlying etiology must be corrected for return of circulation to occur. Medical therapies are unlikely to correct traumatized tissue and restore spontaneous circulation.

If definitive surgical intervention is available, resuscitative thoracotomy may be a reasonable intervention for a subset of trauma patients. This subset includes any traumatic arrest patient with the following features: witnessed arrest in the

emergency department, arrest time less than 5 minutes with penetrating cardiac injury, arrest time less than 15 minutes with penetrating thoracic injury, or any exsanguinating abdominal vascular injury in which secondary signs of life are present (e.g., pupillary reflexes, spontaneous movement, organized electrocardiographic activity). Thoracotomy allows internal cardiac massage and defibrillation, relief of pericardial tamponade, direct control of cardiac or thoracic hemorrhage, and cross-clamping of the aorta. Many of these interventions require a high degree of technical skill and should be attempted only by experienced providers; however, outcomes are predictably poor.

**Status Asthmaticus**

More than 4000 deaths occur annually as a result of asthma. Two general scenarios in decompensated asthma patients most often account for the cardiac arrest. The first is the sudden onset of a severe exacerbation that rapidly worsens and progresses to full cardiopulmonary arrest. The second scenario involves patients with progressive bronchospasm that is unresponsive to maximal therapy. Progressive hypoxia and hypercapnia with metabolic and respiratory acidosis are responsible for the ultimate decline. At times in this setting, complications of therapy such as barotrauma account for the hemodynamic decline.

The mainstay of therapy in treating asthma-induced arrest is overcoming hypoxia and bronchoconstriction. In these cases, endotracheal intubation should be performed rapidly, and barotrauma (primarily pneumothorax) must be avoided. Decreasing tidal volumes to 5 to 6 mL/kg and reducing the ventilatory rate to 8 to 10 breaths/min can avoid excessive increases in lung volumes caused by breath stacking with prolonged expiratory phases. This technique is an extension of controlled hypoventilation, or permissive hypercapnia. If resuscitation is successful with return of spontaneous perfusion, sodium bicarbonate is administered intravenously to maintain the serum pH level greater than 7.15 to 7.20.

External compression of the thorax during the expiratory phase to maximize exhalation has been proposed, but its use remains controversial and it will probably be difficult to coordinate during compressions. Needle or tube thoracostomy decompression should be performed if pneumothorax is detected or suspected. Bilateral decompression for refractory arrest is warranted given the potential for masking the lateralizing signs of pneumothorax.

Standard ALS strategies also apply to dysrhythmias. Epinephrine is likely to be the most useful of the standard drug therapies. Correction of profound acidosis via the empiric use of sodium bicarbonate may be necessary to achieve responsiveness to sympathomimetic agents. The addition of isoproterenol, aminophylline, terbutaline, and magnesium may be considered for improved bronchodilation, but their benefit in patients with asthma-induced cardiac arrest has not been reported, and they are unlikely to achieve success.

**Pregnancy**

Causes of cardiac arrest specific to pregnant patients are maternal hemorrhage, toxemia, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), amniotic fluid emboli, and adverse effects of maternal care, including tocolytic and anesthetic therapies. Pregnancy also increases the likelihood of certain nonobstetric causes, including pulmonary embolism, septic shock, cardiovascular diseases such as cardiomyopathy and myocardial infarction, endocrine disorders, and collagen vascular disease. Traumatic causes of arrest should also be considered because of documented increased rates of abuse and homicide in pregnant women.

Cesarean delivery should be accomplished as soon as cardiac arrest is identified in a pregnant patient. The highest survival rates for infants older than 24 to 25 weeks’ gestational age occurs in deliveries performed within 5 minutes of arrest of the mother. This intervention is most appropriately performed by a multidisciplinary team skilled in emergency obstetric surgery.

Pregnant patients should be placed in the left lateral decubitus position. Displacement of the gravid uterus should be performed by elevating the right hip and lumbar region 15 to 30 degrees from the supine position. Manual displacement of the uterus by lifting it with two hands and directing it toward the upper left part of the patient’s abdomen can be performed before blanket roll placement and afterward to optimize venous return.

**Poisoning**

Toxidromes may be masked in the setting of cardiac arrest because of prolonged hypoxia and hypoperfusion and thus complicate the selection of specific antidotes or therapies. Once poisoning is suspected, consultation with a medical toxicologist or poison control center should be sought if feasible.

In the setting of an unknown toxin or mixed ingestion, standard ALS algorithms are unlikely to be harmful and probably represent the most appropriate course of action. When specific antidotes are required, ACLS is insufficient. If a specific toxin is suspected based on the history or clinical signs, one should consider adding targeted therapies. It is also extremely important to remember that a single reported toxic ingestion is often accompanied by unreported accessory ingestions. Differential diagnoses and treatments must thus be kept broad when targeting treatment. When poisoning is suspected, prolonged resuscitation attempts might be warranted.

**Electrical Injury**

The heart is particularly sensitive to electrical injury. Alternating current is likely to produce VT through a mechanism similar to the R-on-T phenomenon, whereas a lightning strike can produce asystole or VT through depolarization of the myocardium by a direct current shock.

ALS algorithms do not require modification for electrically induced cardiac arrest. The potential for successful resuscitation is higher than that for other causes of cardiac arrest given that these patients are typically younger and lack coexisting cardiopulmonary disease. Trauma and burn care is often required because they are common sequelae of electrical shock and lightning injury.

**Hypothermia**

Severe hypothermia causes marked functional depression of all critical organ systems. Such dysfunction can lead to cardiovascular collapse but may also have a protective effect that allows successful resuscitation. Clinical judgment should prevail in the decision whether to attempt resuscitation. The often-quoted maxim—“one is not dead until he/she is warm
MARDI AND KENDRICK

Submersion Injury and Near-Drowning

Cardiac arrest after submersion is usually due to hypoxia as a result of suffocation, but it may also be secondary to head or spinal cord injury. For this reason, early intubation is suggested if feasible and should be performed with manual stabilization of the cervical spine. Aspiration of large volumes of fluid with submersion is rare, but increased inspiratory and positive end-expiratory pressure may be required to achieve adequate oxygenation because of pulmonary edema.

Routine ALS algorithms should be used for cardiac arrhythmias without modification. Electrolyte and acid-base disturbances are unlikely causes of cardiac arrest in the early manifestations of submersion injury and do not warrant empiric therapy. Correction of acidosis should be considered in patients who later deteriorate during observation. The prognosis depends on the duration of submersion and the severity and duration of hypoxia. Hypothermia and trauma are common confounders of submersion injury, and appropriate therapy should be applied.

POSTRESUSCITATION PHASE

POST–CARDIAC ARREST SYNDROME

Management of resuscitated cardiac arrest patients has undergone significant change in the past decade. The concept of post–cardiac arrest syndrome has been developed. This syndrome, thought to occur in the initial 72 hours after ROSC, is a unique pathophysiologic entity found in patients who have been resuscitated from cardiorespiratory arrest. The primary considerations include CNS injury, myocardial dysfunction, systemic hypoperfusion with reperfusion-related damage, and the precipitating event. Brain injury from ischemia is responsible for many patient deaths, including approximately 70% of patients resuscitated after out-of-hospital arrest and 25% of individuals resuscitated after in-hospital arrest. The basic reasons for CNS injury include a limited tolerance for brain ischemia coupled with a unique response to reperfusion. Brain injury is an ongoing phenomenon, even after successful resuscitation, that usually results from a number of different pathophysiologic events. Injury can continue for 6 to 72 hours after the return of spontaneous perfusion despite adequate systemic blood pressure.

Mechanisms responsible for the CNS injury include the development of cerebral edema, dysfunctional circulation, disruption of the blood-brain barrier, and multiple small infarctions. Cerebral edema alters perfusion, hastens the production of inflammatory mediators, and produces cellular dysfunction. Dysfunctional circulation can occur at the microcirculatory level despite an intact macrocirculation. The cerebral edema and altered microcirculation disrupt the blood-brain barrier, whereas the altered perfusion produces ischemia and multiple small CNS infarctions. Three additional issues contribute to CNS injury: pyrexia, hyperglycemia, and seizure. The final common pathway of CNS injury is neuronal cell death with brain malfunction, poor neurologic recovery, and patient demise.

Myocardial dysfunction has a significant negative impact on survival, and it is both reversible and responsive to therapy. The myocardial dysfunction is not always due to infarction. Most often, myocardial stunning is responsible for the cardiac dysfunction and produces significant and profound reductions in cardiac output. Continued myocardial dysfunction results in respiratory compromise, impaired systemic perfusion, and worsening of multiorgan malfunction. Myocardial dysfunction is usually rapidly apparent after return of perfusion, thus requiring very close hemodynamic monitoring. As the exogenous catecholamines are metabolized once perfusion is restored, hypoperfusion becomes obvious. Hypoperfusion can be worsened by the use of sedative-hypnotic agents for the control of agitation and maintenance of unresponsiveness in a chemically paralyzed patient.

Increasing tachycardia and left ventricular end-diastolic pressure are seen within minutes of ROSC, whereas decreasing mean arterial pressure is not usually apparent for many hours after resuscitation. Hypotension is generally obvious at 4 to 6 hours, reaches a nadir at 8 hours, and classically recovers by 24 to 72 hours. This myocardial dysfunction creates additional tissue hypoxia and acidosis, intensifies the multiorgan injury, and contributes to a significantly increased risk for death.

Reperfusion-related injury results from the whole-body ischemia typical of cardiac arrest and produces a significant
oxygen debt, depletion of energy substrates, and accumulation of waste products. The immunologic and coagulation systems are activated with the release of cytokines and endotoxins and complicated by fibrin deposition with microthrombosis. This component of injury is similar to sepsis syndrome and is manifestly clinical by intravascular volume depletion, impaired vascular autoregulation, coagulopathies, ineffective oxygen delivery to tissues with inefficient tissue oxygen extraction, and increased susceptibility to infection.

Finally, the precipitating event must be considered for effective management of a postresuscitation patient. It is a major determinant of survival with a very broad range of potential events, involves both cardiac and noncardiac causes, and occurs over acute, acute-on-chronic, and chronic periods.

POSTRESUSCITATION MANAGEMENT

Management considerations (Figs. 7.11 and 7.12) must address the following issues: CNS injury, myocardial dysfunction, systemic hypoperfusion, multiorgan failure, and the precipitating cause of the cardiac arrest. Multidisciplinary critical care support along with appropriate respiratory and hemodynamic support is vital. Two specific treatment considerations, therapeutic (induced) hypothermia and emergency coronary reperfusion, must be emphasized in these resuscitated patients.

Therapeutic hypothermia (TH), or induction of lower body temperatures in unresponsive patients resuscitated from cardiac arrest, is strongly encouraged in certain individuals. The AHA notes that “…therapeutic hypothermia in the resuscitated cardiac arrest patient can markedly improve outcome… both in terms of rates of survival and neurologic status.”

TH is currently recommended for victims resuscitated after out-of-hospital cardiac arrest with initial rhythms of either pulseless VT or VF who remain unconscious. TH should also be considered in patients resuscitated from cardiac arrest associated with other initial rhythms (i.e., PEA and asystole) and in survivors of in-hospital cardiac arrest.

The actual beneficial mechanisms for TH are not fully known, but the basic accepted mechanism involves suppression of the chemical cascade associated with the total-body ischemia and reperfusion injury. These mechanisms probably involve a number of different protective processes, including a reduction in the metabolic rate, oxygen use, and CNS electrical activity. TH probably interrupts the injury process at many points in the pathophysiologic response to cardiac arrest and subsequent reperfusion. Regardless of the modes of action of this intervention, TH has been demonstrated to provide CNS protection, reduce the incidence of multiorgan failure syndrome, increase survival, and improve functional abilities. The outcome after cardiac arrest with our present abilities remains suboptimal. Use of TH can increase the rate of functional survival, but it is not a miracle cure.

Indications for TH include the following qualifiers: nontraumatic cardiac arrest, resuscitation with spontaneous perfusion, unresponsive status, and age between 18 and 75 years. Any set of indications for a clinical therapy is open to discussion and further consideration. Several qualifications are needed. First, primary cardiac arrest is the most appropriate indication for TH. Noncardiac causes of arrest such as sepsis, a CNS event, ingestion, trauma, and others are unlikely to benefit. Primary cardiac arrest, or an event related to cardiac arrhythmia that is due to a cardiac cause, is the most appropriate for TH. Certain other victims of noncardiac causes of arrest can be considered for TH. These potential additional indications include victims of a sudden event that when corrected does not leave a significant, lasting injury or process other than post–cardiac arrest syndrome. Consideration should be made for patients with sudden choking or hanging that leads to respiratory failure and subsequent cardiac arrest.

Second, resuscitated patients should be relatively stable in terms of the ABCs, which means that they are endotracheally intubated and undergoing mechanical ventilatory support with...
intact perfusion. Significant difficulties with oxygen and ventilation must be addressed before the use of TH. Perfusion must be intact, whether spontaneously or supported by intravenous fluids, vasopressors, or inotropes, and it should be understood that significant difficulties in maintaining perfusion should delay the use of TH. Third, the patient must be unresponsive. Multiple different descriptors have been used to describe the patient’s mental status, including unresponsive, comatose, or possessing a Glasgow Coma Scale score of 8 or less.

The last basic indication is age. The most appropriate patient is an adult. The most frequently listed age range is 18 to 75 years, thus removing all children and the extreme elderly from consideration. This age indication is at best a guide, and certain younger and older patients represent appropriate candidates for TH. A major consideration in these two excluded groups is that a primary cardiac etiology is less often the primary causative event in the development of cardiac arrest. Sepsis, trauma, ingestion, and other conditions are frequent primary causative events in the development of cardiac arrest. Clinician judgment with consideration of individual patient issues will exclude these candidates from consideration of TH. Clinician judgment with consideration of individual patient issues will be the most appropriate determinant of therapy with respect to the age extremes.

A thorough discussion of the process and technique of cooling is beyond the scope of this chapter. Highlights of TH include the following issues:

- Patients should be cooled as soon as possible after ROSC, ideally within 4 to 6 hours. Cooling should last for approximately 18 hours once the target temperature has been reached.
- The goal temperature is 32° C to 34° C.
- The patient is probably mechanically ventilated via an ETT.
- Pain medication and sedative agents are probably required for patient comfort and safety. Chemical paralytic agents are used with caution because seizures cannot be detected as easily.
- Shivering should be avoided if at all possible because of the related heat production, and appropriate treatment should be provided if it develops.
- Biometric surveillance should include an electrocardiogram, blood pressure, core temperature, oxygen saturation, and end-tidal CO2 monitoring. Continuous electrocardiographic monitoring can also be considered. Laboratory studies should include electrolytes and serum glucose.
- The most appropriate cooling method is debatable. Two basic approaches have been advocated, but thus far neither therapy has proved to be superior. Rapid infusion of 2 L of chilled normal saline (4° C) represents the least challenging approach. The chilled saline is used in conjunction with cooling blankets and ice packs applied to the neck, armpits, groin, and other areas. The other technique, which is both more invasive and more expensive, involves the use of an intravascular cooling machine. This technique, once the intravascular catheter has been placed, is easier to use in terms of reaching the target temperature and maintaining this temperature.
- If instability develops, all cooling must be halted immediately and appropriate therapy initiated to address the current clinical situation.

It has been suggested that emergency coronary reperfusion, provided as soon as possible after ROSC from cardiac arrest, can not only improve survival but also increase the opportunity for more meaningful survival. Emergency coronary reperfusion can be achieved by fibrinolysis or percutaneous coronary intervention (PCI), with PCI being the preferred technique.

The primary indications for such an intervention included ST-segment elevation myocardial infarction (STEMI) and new-onset left bundle branch block. Patients who demonstrate one of these findings on electrocardiography, either before or after arrest, are candidates for emergency coronary reperfusion. The majority of cases of primary cardiac arrest are associated with acute coronary syndromes, and it would seem reasonable to assume that emergency coronary reperfusion in patients with ROSC would be associated with improved outcomes. The AHA issued a policy statement in 201037 supporting the use of immediate catheterization in survivors of cardiac arrest who demonstrate electrocardiographic evidence of STEMI: “Patients resuscitated from [out-of-hospital cardiac arrest] with STEMI should undergo immediate angiography and receive PCI as needed.”

These two classic findings represent the primary indications for emergency coronary reperfusion. More recent investigation of this therapy has suggested that all patients suspected of having primary cardiac arrest can be considered for emergency coronary reperfusion. It is well known that the electrocardiogram is far from perfect in demonstrating evidence of AMI. Use of electrocardiography to determine which patients will benefit from emergency coronary reperfusion might potentially lead to some individuals missing out on such a benefit. The absence of ST-segment elevation after ROSC does not reliably rule out the presence of acute coronary artery occlusion.37,38 There has been increasing support in the literature39,40 for early coronary angiography in even these patients without ST-segment elevation.

The combination of TH and emergency coronary reperfusion offers very promising results. This combination of postresuscitative therapy has demonstrated survival rates approaching 50% with intact or nearly intact functional status, and both PCI and TH can be safely performed simultaneously.41

Finally, a multidisciplinary critical care team is strongly encouraged. Interventions such as TH, hemodynamic optimization, ventilation strategies, seizure management, serum glucose maintenance, and PCI are all recognized to be important considerations in these patients.

Medical centers that are well equipped, aggressive, and experienced in the use of post-arrest interventions are more likely to demonstrate the best outcomes. It has been suggested that outcomes in victims of cardiac arrest are better at facilities that care for at least 50 such cases per year.37,42 Should postresuscitation care be regionalized? The Ontario Prehospital Advanced Life Support database demonstrates that transport time is not associated with outcome after cardiac arrest, thus suggesting that regionalization of this care might be appropriate.43

CHAPTER 7 MANAGEMENT OF CARDIAC ARREST AND POST–CARDIAC ARREST SYNDROME

REFERENCES

Trauma Resuscitation
Trevor J. Mills

The American College of Surgeons and many emergency medical service systems have adopted algorithms based on clinical signs and symptoms for transport to a trauma center. These signs and symptoms identify patients at high risk for injury and are based on early physiologic changes, anatomic criteria, or a mechanism with a high likelihood of significant injury (Box 8.2). Along with the trauma center criteria, in each of the major anatomic areas there are important clues to potentially life- and limb-threatening injuries (Table 8.1).

Head injuries may result in a decreased level of consciousness leading to loss of airway protection or respiratory drive. Head injuries can also precipitate hemorrhagic shock as a result of the abundant vascular supply of the face and scalp. Because of their proportionally larger heads, children can lose a significant amount of blood with closed intracranial hemorrhage. For further specific evaluation and treatment of head injuries, see Chapter 73.

Injury to the face, including an unstable midface, or trauma to the oropharynx may cause direct airway compromise. Facial injuries can also lead to aspiration of blood, tissue, teeth, and bone. Early or prophylactic intubation should be considered if impending airway compromise is suspected or imminent.

High spinal injuries may lead to loss of airway control, loss of the respiratory drive, or hemodynamic instability as a result of spinal shock. Paralysis may also make evaluation of other injuries extremely difficult.

Thoracic injuries can result in direct tracheal, pulmonary, or cardiac damage and lead to significant intrathoracic hemorrhage or direct respiratory compromise.

Because the abdominal cavity can hold a large amount of blood, solid organ or vascular injury in the abdomen can easily result in hemodynamic collapse. Pelvic fractures are also a potential site of significant blood loss from uncontrolled venous bleeding.

Even isolated extremity injuries can result in arterial hemorrhage or considerable blood loss in the form of fracture-related hematomas. Fractures may cause delayed respiratory distress because of fat emboli.

A history of a significant injury mechanism, even without apparent injury, requires a thorough trauma evaluation. Examples include penetrating trauma to the head, neck, chest, abdomen, and proximal part of the extremities; significant

KEY POINTS

- The approach to trauma resuscitation is based on the assumption that all severely injured patients can initially be evaluated and treated with the same set of guidelines.
- Regardless of the specific injury, these guidelines focus on the broader concept of sustaining life by maximizing oxygenation, ventilation, and perfusion—the ABCs of trauma resuscitation.

EPIDEMIOLOGY

Traumatic injury is a significant cause of death and disability worldwide, especially in the younger population. In the United States, unintentional injury is the leading cause of death in the age range between 1 and 44 years. Approximately half of trauma-related deaths occur at the time of injury or before the patient reaches the hospital. Another 30% of traumatic deaths may occur in the first few hours after the event. It is this severely injured, but salvageable population that should be immediately evaluated and treated with the trauma resuscitation paradigm.

PERSPECTIVE

In a traumatized patient, loss of the airway or respiratory failure (or both) may be due to direct injury to the head, face, oropharynx, neck, trachea, bronchi, chest, or lungs. Alternatively, secondary airway or respiratory compromise (or both) may be caused by injury that results in loss of muscle control or respiratory drive; aspiration of blood, tissue, teeth, or gastric contents; or air or fat emboli.

Shock in trauma patients is often due to hemorrhagic blood loss, but it may also be caused by damage to the heart, great vessels, or lungs or by hemodynamic compromise from fat emboli, ischemia, or neurogenic shock (Box 8.1).
falls; rollover or high-speed motor vehicle collisions; and
cyclists or pedestrians struck by a motor vehicle.

Some patient populations are more likely to have life-
threatening injuries without obvious signs and symptoms. 
This group includes the elderly, the very young, patients with
coagulopathies, and those with reduced physiologic reserve
because of chronic disease or acute intoxication.

Because trauma resuscitation is a “one size fits all comers”
approach to the undifferentiated patient, there is no classic
differential diagnosis. It is important to remember that a
patient who arrives in traumatic shock may have a concurrent
acute medical condition, such as acute myocardial infarction,
hypoglycemia, or intoxication, that may confound the trauma
evaluation.

**Box 8.1 Causes of Airway or Respiratory Compromise and Shock in Trauma Patients**

Causes of Traumatic Airway or Respiratory Compromise

- Direct trauma to the face, oropharynx, neck, trachea, or pulmonary system resulting in obstruction of the airway or respiratory compromise
- Indirect injury as a result of brain or spine injury (loss of drive), fat or air pulmonary emboli, or aspiration of blood or gastric contents

Causes of Shock in Traumatized Patients

- Hemorrhagic shock
- Injury to the heart (cardiac contusion, valve rupture, penetrating trauma)
- Compression of the heart as a result of tamponade or tension pneumothorax
- Cardiogenic shock (ischemia, arrhythmias)
- Neurogenic or spinal shock

**RED FLAGS**

- Early alterations in vital signs
- Altered mental status
- Patient at either extreme of age
- Prolonged time on the scene or transport time (extrication of the patient or entrapment)
- Weakness or paralysis

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Because trauma resuscitation is a “one size fits all comers” approach to the undifferentiated patient, there is no classic differential diagnosis. It is important to remember that a patient who arrives in traumatic shock may have a concurrent acute medical condition, such as acute myocardial infarction, hypoglycemia, or intoxication, that may confound the trauma evaluation.
consideration for the patient’s age, physiologic reserve, and underlying chronic conditions. (See the Red Flags box.)

Although performance of the primary survey should be fluid and may involve multiple individuals performing multiple actions simultaneously, the components of the primary survey can be broken down into six sequential steps: airway, breathing, circulation, disability, exposure, and fingers or Foley (ABCDEF) (see Fig. 8.1 and Priority Actions box).

If an indication for intervention is discovered during the primary survey, treatment should be initiated and the primary survey restarted from the beginning (Fig. 8.2).

The primary survey starts as the patient enters the room by questioning the patient, evaluating for airway patency, and then directly visualizing the facial structures, neck, and oropharynx (A).

Breathing or ventilatory status can then be evaluated through visual examination of the neck and thorax, auscultation of all lung fields, and palpation of the chest. Palpation can provide clues to rib injury, open or sucking chest wounds, and subcutaneous air in the neck and chest. The respiratory rate, patient report of chest pain or shortness of breath, and pulse oximetry also contribute to this phase of the resuscitation (B).

Evaluation of circulatory status (C) involves a judgment of the patient’s general appearance, heart rate and blood pressure, extremity pulses, and nail bed capillary refill. If the patient has not been connected to a continuous heart rate and blood pressure monitor, this step should be taken at this time.

The next step is a brief neurologic examination (for disability—D). At this point, assessment for disability does not include a detailed neurologic examination but instead a look at the gross motor movement of all extremities and the patient’s level of alertness. The most common tool for evaluating global neurologic function is the Glasgow Coma Scale (GCS) (Table 8.2). Three systems are evaluated: eye opening, verbal response, and motor response. The closer that each function is to baseline, the higher the score for each system. A GCS score of 13 or higher correlates with mild brain injury, 9 to 12 with moderate injury, and 8 or less with severe brain injury.

injury. A GCS score lower than 8 is an indication for immediate airway control. Thus, the GCS can help in evaluating the need for intubation, provide a marker for serial neurologic examinations, and promote clear communication with consultants regarding patient status.

Completion of the primary survey involves exposure of the entire patient (E) in a way that prevents hypothermia; coordinated in-line cervical spine immobilization should be maintained during this procedure.

The F (fingers and Foley) step of the primary survey involves consideration of placement of a Foley bladder catheter and orogastric tube, a rectal examination, and a bimanual vaginal examination. Even though there has been a trend away from the dogmatic approach to use of a rectal and Foley catheter for everyone who enters the trauma algorithms, these measures are still indicated in certain patients, especially those who are obtunded, have a high likelihood of bowel injury, or are hemodynamically unstable.

### PRIORITY ACTIONS

**Primary Survey**

A = Airway control  
B = Breathing: Maximize ventilation  
C = Circulation: Stabilize hemodynamic status  
D = Disability: Evaluate mental status and perform a neurologic examination  
E = Exposure: Completely undress and examine the patient  
F = Fingers and Foley: Perform orogastric, bladder catheter, vaginal, and rectal examinations

**Secondary Survey**

Head-to-toe physical examination  
Focused abdominal sonography examination for trauma (FAST)  
AMPLE (allergies, medications, past medical history, last meal, events of the injury)  
Laboratory tests and radiology

### SECONDARY SURVEY

The secondary survey consists of an expanded history, a head-to-toe examination, focused sonography, and initiation of the standard trauma radiology and laboratory tests. If possible, the history should be taken from the patient or the prehospital personnel (e.g., emergency medical technicians) who delivered the patient to the hospital. The key points of the history can be remembered with use of the mnemonic AMPLE, which stands for allergies, medications, past medical history, last meal, and events of the injury.

The head-to-toe examination involves a second review of the airway and pulmonary examination, including an expanded physical examination to identify further injury.

In a hypotensive patient, because the abdominal cavity can conceal enough blood to be an immediate threat to life, part of the secondary survey is the focused abdominal sonography examination for trauma (FAST). FAST can be done in the resuscitation area. Because it is faster and less invasive to obtain, FAST has replaced diagnostic peritoneal lavage (Table 8.3).

Likewise, the more sensitive and specific computed tomography (CT) of the abdomen should wait until the end of the secondary survey because CT scanning may be time-consuming and takes the patient out of the resuscitation area.

The advantage of a standardized approach to trauma radiology is that it can identify life-threatening injuries that may necessitate immediate attention. Significant cervical spine fractures may lead to airway compromise, loss of ventilatory drive, or spinal shock. The chest radiograph may identify a treatable condition, such as a large pneumothorax, hemothorax, or pulmonary contusion. Pelvic radiology can identify an open-book pelvic fracture, which may lead to hemorrhagic shock.

For many years, standard trauma series radiographs included plain films of the cervical spine, the chest, and the pelvis. Currently, the only standard plain film is the chest radiograph. The cervical spine radiograph has been replaced by CT of the cervical spine, but a rare exception is the use of screening films for penetrating trauma (Fig. 8.3). In the majority of trauma patients, the pelvic radiograph has been replaced by CT of the abdomen and pelvis with reconstructed images of the bony pelvis. In some patients, such as those who may need immediate pelvic binding to temporize hemorrhage or penetrating injury to the pelvis, a one-view pelvic radiograph in the trauma suite is still useful. Thus, the new standard trauma radiology series involves a chest radiograph and CT scans of the head, cervical spine, and abdomen and pelvis. Chest CT is indicated for a widened mediastinum or if vascular injury is suspected. Early consideration of the need for CT angiography of the neck or extremities should be undertaken to minimize the load of contrast media.

The key to maximizing the success of trauma resuscitation is early diagnosis and treatment of injuries. The extent of damage from many significant injuries can be reduced with early intervention, including cervical spine immobilization throughout the resuscitation.

For a severely injured patient, the primary airway intervention is orotracheal intubation by rapid-sequence induction. Indications for airway intervention include airway protection, expected clinical course, and the need for assisted ventilation or oxygenation (Box 8.3).

Alternative methods of orotracheal intubation include nasotracheal intubation, cricothyrotomy, laryngeal mask airway, retrograde intubation, and transtracheal jet insufflation. At a minimum, 100% oxygen should be administered via a nonrebreather mask to maximize tissue oxygenation.

After the airway is controlled, respiratory status is evaluated. Several alterations in ventilation mandate immediate intervention (Table 8.5).

After the airway and breathing are evaluated and stabilized, hemodynamic status should be evaluated. During trauma

**TREATMENT: HOSPITAL**

The key to maximizing the success of trauma resuscitation is early diagnosis and treatment of injuries. The extent of damage from many significant injuries can be reduced with early intervention, including cervical spine immobilization throughout the resuscitation.

For a severely injured patient, the primary airway intervention is orotracheal intubation by rapid-sequence induction. Indications for airway intervention include airway protection, expected clinical course, and the need for assisted ventilation or oxygenation (Box 8.3).

Alternative methods of orotracheal intubation include nasotracheal intubation, cricothyrotomy, laryngeal mask airway, retrograde intubation, and transtracheal jet insufflation. At a minimum, 100% oxygen should be administered via a nonrebreather mask to maximize tissue oxygenation.

After the airway is controlled, respiratory status is evaluated. Several alterations in ventilation mandate immediate intervention (Table 8.5).

After the airway and breathing are evaluated and stabilized, hemodynamic status should be evaluated. During trauma
resuscitation, it is imperative that IV access be established immediately to facilitate rapid transfusion or administration of blood products (18-gauge or larger IV line). Ideal guidelines recommend a minimum of two working IV sites. Alternatives to large-bore peripheral IV access are intraosseous lines, central lines, and venous cutdown lines. In a hypotensive adult patient with trauma, an initial bolus of 2 L of warm normal saline or lactated Ringer solution is a reasonable starting point. In children, a 20-mL/kg bolus should be used. If the traumatized patient remains hypotensive after the initial bolus, transfusion of type O-negative or type-specific blood should be considered. A caveat to this statement is a patient who has sustained penetrating trauma to the chest or abdomen, in whom a short period of permissive hypotension (on the way to the operating room) may improve survivability by not disrupting an internal tamponade. Recent military and trauma center practice has championed aggressive blood and fresh frozen plasma resuscitation in a 1:1 ratio in patients in hemorrhagic shock. When possible, manual pressure or military tourniquets should be used in conjunction with fluid or blood resuscitation to temporize hemorrhage.

Once the primary survey is completed and the patient is stabilized, the secondary survey is used to unveil the remaining injuries. Patients may then require specific care of individual injuries or specialty consultation as needed.

**TIPS AND TRICKS**

**Intubation**
- Prepare the equipment.
- Preoxygenate the patient with 100% O₂.
- Evaluate the oropharynx.
- Use an end-tidal CO₂ detector.
- Have an alternative method available.

**Chest Tube Placement**
- Extend the arm on the side of the chest tube above the head.
- Use local anesthesia.
- Have a cell saver in a pleural evacuation unit (Pleurovac) before patient arrival.

**Intravenous Access**
- Place the access site away from injuries.
- Consider an external jugular vein approach.
- Consider femoral central venous access.

**Focused Abdominal Sonography for Trauma (FAST)**
- Clamp a Foley catheter.
- Perform serial examinations if the vital signs change.

**BOX 8.3 Indications for Airway Intervention**

- Decreased level of consciousness (Glasgow Coma Scale score < 8)
- Extreme agitation
- Presence of or impending airway obstruction
- Presence of or impending compromise of ventilation
- Need for immediate surgical intervention
- Hemodynamic instability

**Table 8.5 Indications for Respiratory Intervention in Patients with Trauma**

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

All patients requiring trauma evaluation and treatment because of anatomic or physiologic trauma center criteria (see Box 8.2) must be admitted to the hospital. Patients who meet the mechanism criteria only and in whom thorough evaluation identifies no injuries may be candidates for discharge with careful warnings and comprehensive discharge planning.

**DOCUMENTATION**

The following categories of information should appear in the documentation for every patient with trauma:

**History**
- Prehospital history
- Detailed mechanism (e.g., speed of the vehicle, height of the fall)
- Circumstances (e.g., damage to the vehicle, type of weapon)
- Timing of the event
- Time until arrival at the emergency department
- Concurrent medications
- Drug or alcohol use
- Past medical history
- Last meal
- Immunizations
- Previous operations

**Physical Examination**
- Primary survey and interventions
- Head-to-toe examination

**Studies**
- Emergency department interpretation of computed tomography scans and radiographs
- Results of focused abdominal sonography examination for trauma (FAST)

**Medical Decision Making**
- Reasons to pursue or not pursue a work-up for each injury
- Consultation by surgical or other subspecialists

**Procedures**
- Each procedure performed (document in full)

**Patient Instructions**
- Discussion of injuries and potential outcomes with the patient or the patient’s family (or both)
Patients with major trauma often have a long recovery period with a high risk for permanent deficits. Once stabilized, a team approach consisting of occupational therapy, physical therapy, nutrition, and mental health can help speed recovery and improve the long-term outcome.

Sonography for Trauma

Christine Butts and Justin Cook

Ultrasound for the evaluation of trauma patients was one of the first applications of bedside ultrasound used by emergency physicians (EPs). The FAST examination (originally, focused abdominal sonography for trauma; currently, focused evaluation with sonography for trauma) was developed initially as a noninvasive modality for the initial triage of patients with hypotensive blunt abdominal or thoracic trauma. Its purpose was to rapidly identify patients with free intraperitoneal fluid or with pericardial effusion. However, over the past 20 years, FAST has evolved considerably to include the evaluation of patients after normotensive blunt trauma and penetrating trauma. Implementation of other bedside ultrasound advances has led to the development of E-FAST (or extended FAST). E-FAST involves evaluation of the inferior vena cava (IVC) for overall intravascular fluid status and assessment of the chest for pneumothorax and pleural effusion.

WHAT WE ARE LOOKING FOR

Following trauma, particularly blunt trauma, patients may be hemodynamically unstable because of bleeding from multiple sites. It can frequently be difficult to ascertain where the patient’s injuries lie based on the history and physical examination alone. FAST was designed to identify possible sources of bleeding that result in instability. It relies on the premise that free fluid (blood) within the peritoneum will accumulate within the most gravity-dependent areas. These areas are the right upper quadrant between the liver and kidney (pouch of Morison), the right paracolic gutter, the left upper quadrant between the spleen and kidney, the potential space between the spleen and diaphragm, the left paracolic gutter, and the pelvis. FAST seeks to evaluate these areas quickly for the presence of free fluid. It also seeks to evaluate the pericardial sac for the presence of pericardial effusion and possible cardiac tamponade. The presence of cardiac activity or the status of overall cardiac function can also be assessed.

LITERATURE REVIEW

Multiple studies have demonstrated the utility of FAST for the evaluation of patients after blunt abdominal trauma. One of the first studies to highlight FAST by EPs was performed by Ma and Mateer in 1995. This study evaluated ultrasound for detection of free fluid not only in the peritoneum but also in the pericardium, the retroperitoneal space, and the pleural...
cavity. The authors evaluated a total of 975 cavities and calculated a sensitivity of 90%, a specificity of 99%, and an accuracy of 99%. This study demonstrated that with training, EPs are capable of identifying free fluid with high sensitivity and specificity.

Subsequent studies focusing on FAST have found variable results ranging from sensitivities of 79% to 100% and specificities of 95.6% to 100%. Although calculated sensitivities and specificities have been variable across studies, one finding that seems consistent is that both sensitivity and specificity appear to increase in hypotensive patients.

Conversely, a Cochran review published in 2005 found “insufficient evidence from RCTs [randomized controlled trials] to justify promotion of ultrasound-based clinical pathways in diagnosing patients with suspected blunt abdominal trauma.” These findings have been controversial, and a similar literature review by Melniker found “the FAST examination, adequately completed, is a nearly perfect test for predicting a ‘Need for OR’ in patients with blunt torso trauma.”

One finding that has appeared consistently in most studies is that although FAST is sensitive and specific for the detection of intraperitoneal free fluid, it has poor results when used in attempts to localize solid organ injury.

Ultrasound has been shown to be a reliable study for the evaluation of traumatic pericardial effusions. Mandavia et al. found that EPs with training in echocardiography had a sensitivity of 96%, a specificity of 98%, and an overall accuracy of 97.5% for this indication.

**HOW TO PERFORM A FAST EXAMINATION**

FAST consists of ultrasound views of four primary areas, the right and left upper quadrants of the abdomen, the pelvis, and a view of the pericardium from the subxiphoid area.

A low-frequency transducer is typically used to ensure proper depth of penetration.

**SUBXIPHOID VIEW**

To evaluate the subxiphoid view of the heart, the transducer is placed just below the subxiphoid process and aimed toward the patient’s left shoulder (Fig. 9.1). It is frequently necessary to apply some pressure to the upper part of the patient’s abdomen to enable the sonographer to look “up” into the patient’s chest. It is also helpful to think of the transducer as a flashlight and imagine shining it toward the left side of the patient’s chest. Another helpful tip for beginning sonographers is to increase the depth if at first the heart is not seen in full. A four-chamber view of the heart should be sought (Fig. 9.2). Specifically, the bright white (or hyperechoic) outline of the pericardium should be sought to evaluate for the presence of pericardial effusion.

**RIGHT UPPER QUADRANT**

The right upper quadrant should be evaluated in both the coronal and transverse planes. To begin, the transducer is placed on the patient’s midaxillary line between the 8th and 11th ribs (Fig. 9.3). This position should be adjusted as needed to overcome rib shadowing and to obtain the best image possible. Aiming the indicator toward the patient’s head will yield a coronal image. The interface between the liver and kidney (pouch of Morison) and the potential spaces around this area should be thoroughly evaluated for the presence of free fluid (Fig. 9.4). This can be done by sweeping the transducer anteriorly and posteriorly. Moving the transducer superiorly a rib space or two will usually allow a view of the echogenic diaphragm curving over the dome of the liver. The area superior to the diaphragm, the costophrenic recess, can be evaluated for the presence of pleural fluid as well. Once a coronal image has been obtained, the transducer should be rotated so that the indicator points toward the patient’s right to obtain a transverse view. Although such placement frequently provides an adequate view, it is often helpful to angle the transducer on a
to evaluate the interface between the kidney and spleen but also to seek the interface between the spleen and diaphragm (Fig. 9.6). This aids in viewing the costophrenic recess for free pleural fluid, as well as the subphrenic recess, where free peritoneal fluid frequently collects. Again, once the coronal view has been obtained, the transducer should be swept anteriorly and posteriorly to fully assess the left upper quadrant. After the coronal plane has been viewed, the transducer should be rotated so that the indicator faces the patient’s right. It may be helpful to place the transducer at a slight angle to avoid any artifact created by the ribs. Once the interface between the kidney and spleen is found, the transducer should be swept inferiorly and posteriorly to evaluate this region in full.
SECTION I  RESUSCITATION SKILLS AND TECHNIQUES

PELVIS
The final component of the basic FAST examination is evaluation of the pelvis. The transducer should be placed just superior to the pubic symphysis. Beginning in the transverse plane, the indicator on the transducer should be facing toward the patient’s right (Fig. 9.7). The bladder is easily identified in this orientation as a rectangularly shaped object filled with dark, anechoic urine, especially if the ultrasound can be performed before placement of a urinary catheter (Fig. 9.8). Although the bladder is generally identified quickly, the evaluation should proceed further and the bladder be used as an acoustic window to view the dependent portions of the pelvis. This can be done by tilting the transducer toward the patient’s feet and back upward or more superiorly. The transducer can then be rotated toward the patient’s head to view the same area in a sagittal orientation (Fig. 9.9). In this plane the bladder has a triangular appearance (Fig. 9.10). Complete evaluation of the potential spaces of the pelvis can be achieved by tilting the transducer from side to side.

Fig. 9.7  Placement of the transducer for evaluation of the pelvis in a transverse orientation. Note that the indicator is pointing toward the patient’s right. The transducer should be placed just superior to the pubic symphysis.

Fig. 9.8  Normal pelvis as viewed in a transverse orientation. In this image the bladder is clearly seen as a rectangularly shaped fluid collection. Its clearly defined walls distinguish it as the bladder as opposed to free fluid.

Fig. 9.9  Placement of the transducer for evaluation of the pelvis in a sagittal orientation. Note that the indicator is pointing toward the patient’s head. The transducer should be placed just superior to the patient’s pubic symphysis.

Fig. 9.10  Normal pelvis as viewed in a sagittal orientation. In this image the bladder is seen as a triangular fluid collection. Just deep to the bladder, the fundus of the uterus can be seen pushing into its posterior wall.
NORMAL AND ABNORMAL FINDINGS

The primary purpose of FAST is to identify free fluid either within the peritoneum or within the pericardium. Free fluid, although it may accumulate in a number of dependent areas, is fairly reliable in its appearance. Fluid is identified as black on ultrasound, and most free fluid, in this case blood, will have a black appearance. Bleeding that has begun to form a clot is less fluid-like in its consistency and may appear as varying shades of gray.

When evaluating the subxiphoid view of the heart, the bright white, echogenic outline of the pericardium should be sought (see Fig. 9.2). Normally, the pericardium should closely abut the ventricle. Free fluid will be seen as a black collection between the pericardium and the ventricles of the heart (Fig. 9.11). Typically, fluid will first accumulate in the most dependent part of the pericardial sac and can thus be seen deep to the left ventricle. It should be noted that the amount of fluid seen may appear underwhelming on first inspection. It is important to realize that a smaller amount of fluid is needed to cause cardiac tamponade in a trauma patient. This is due to the rapid accumulation of free fluid within the pericardial sac, which quickly overcomes the ability of the fibers of the pericardium to stretch to accommodate increasing pressure.

In the right upper quadrant, free fluid most commonly accumulates in the area between the liver and kidney (pouch of Morison). Acute hemorrhage will be seen as an anechoic (black) stripe of varying size in this potential space (Fig. 9.12).

Free fluid in the left upper quadrant appears much the same as in the right upper quadrant. It may appear as an anechoic stripe between the spleen and kidney. However, the potential space between the spleen and the diaphragm is a common location for free fluid to accumulate and may be overlooked without careful evaluation (Figs. 9.13 and 9.14).

In the pelvis, free fluid will accumulate in the gutters surrounding the bladder (Fig. 9.15). The bladder can be distinguished from free fluid by noting the rectangular shape of the bladder. Free fluid is amorphous and will appear to seep into the gutters of the pelvis, whereas the bladder is either a rectangular (transverse) or triangular (sagittal) shape, depending on the imaging plane chosen.

PITFALLS

The bedside sonographer may encounter both technical and diagnostic challenges while performing FAST.

Diagnostic challenges frequently arise from misuse or incorrect interpretation of the FAST examination. FAST was designed to evaluate the presence of free fluid and pericardial effusion and is most sensitive when used for this purpose, particularly in hypotensive blunt trauma patients. It does not
fare as well when used to either diagnose the location of injury or rule out injury in normotensive or penetrating trauma patients.

The primary technical challenge faced by the sonographer is overcoming artifact. Subcutaneous air, bowel gas, or air in the stomach may make performing a complete FAST examination difficult.

Misidentification of normal structures may also cause falsely positive FAST findings. A full stomach, the IVC, and the gallbladder may appear similar to fluid collections. Knowledge of anatomy and experience with the normal appearance of the structures may minimize this mistake.

E-FAST EXAMINATION

The extended FAST, or E-FAST, is a relatively new addition to the standard FAST protocol and includes views of the lungs for pleural fluid and pneumothorax and views of the IVC to estimate the volume status of the patient.

LITERATURE REVIEW

Ultrasound of the chest shows potential as a rapid tool for diagnosing the presence of pleural fluid and pneumothorax. A prospective study of 240 trauma patients was retrospectively analyzed and published by Ma and Meteer in 1997. This study found an overall sensitivity of 96.2%, specificity of 100%, and accuracy of 99.6% for detection of hemothorax. Interestingly, the authors concluded that “Ultrasonography is comparable to the initial chest radiograph for accuracy in detection of hemothorax” and that its use may result in more rapid diagnosis in trauma patients. Similarly, the use of ultrasound for detection of pneumothorax has also yielded positive results, with multiple studies reporting a range of sensitivities from 95.3% to 100% and specificities from 78% to 99.2%. Specifically, the study of Blaivas et al. evaluated ultrasound and supine chest radiography head to head and found ultrasound to have higher sensitivity (98.1% for ultrasound versus 75.5% for chest radiography) and similar specificity (99.2% for ultrasound versus 100% for chest radiography).

Ultrasound of the IVC has also been examined as an indirect measure of central venous pressure (CVP). A study by Randazzo et al. in 2008 compared CVP estimated by EPs using ultrasound of the IVC with that determined by cardiologists using formal echocardiography. Overall, they found a 70.2% rate of agreement, with most agreement occurring in patients with high CVP (83.3%). A later study by Nagdev et al. in 2010 compared the caval index (percent collapse of the IVC with inspiration) to the standard FAST protocol and includes views of the lungs for pleural fluid and pneumothorax and views of the IVC to estimate the volume status of the patient.

HOW TO SCAN AND SCANNING PROTOCOLS

The lungs and pleural recesses can be evaluated for the presence of fluid, such as occurs with hemothorax, and for the presence of pneumothorax. The pleural recesses should be viewed while the right and left upper quadrants of the abdomen are viewed in the coronal orientation as part of the traditional FAST examination. Moving the transducer more superiorly, from the 8th through the 11th rib interspaces to the 6th to 9th rib interspaces, will usually allow a clear image of the bright white, echogenic diaphragm arcing over the liver or spleen (Fig. 9.16). To the left of the diaphragm, the costophrenic recess can be studied for the presence of fluid.

NORMAL AND ABNORMAL FINDINGS

Pneumothorax is chiefly identified by watching the pleural interface for the presence of sliding. When the lung is viewed with a high-frequency transducer, the visceral and parietal pleura interface is seen as a bright white line deep to the ribs. It should normally be seen sliding back and forth with respiration. When pneumothorax is present, the appearance of sliding is disrupted and the pleura appears as a stationary hyperechoic line (Video 1).

The anterior surface of the lung can also be evaluated for pneumothorax. A high-frequency transducer is best suited for this purpose because it offers a clearer image of the interface between the visceral and parietal pleura. The transducer should be placed in the sagittal orientation, with the indicator pointing toward the patient’s head, in the second or third intercostal space in the midclavicular line. In this view the ribs can be seen with acoustic shadowing extending behind them. Slightly deep to the ribs, the interface of the parietal and visceral pleura can be seen as an echogenic, white horizontal line that slides back and forth with respiration (Video 1).

The IVC can be viewed as it courses behind the liver toward the right atrium. The size and movement of the IVC can be used to estimate the overall fluid status of the patient. Again using a low-frequency transducer to obtain adequate depth of penetration, the IVC is typically seen in the epigastric area. The transducer should be placed in a sagittal orientation, just to the patient’s right, with the indicator pointing toward the patient’s head. Tilting the transducer toward the patient’s head will best use the liver as an acoustic window. The IVC can be seen as a longitudinal tube terminating in the right atrium of the heart (Fig. 9.17). It should be evaluated for overall size and for changes with respiration.
Fig. 9.17 Longitudinal image of the inferior vena cava (IVC) as it courses behind the liver and toward the right atrium. The overall size and respiratory variation of the IVC provide clues to the overall intravascular status of the patient.

Fig. 9.18 Coronal image of the right upper quadrant demonstrating a pleural effusion. The diaphragm can be seen as a hyperechoic line arcing over the liver. To the left of the liver (more superior), an anechoic fluid collection is seen.

Table 9.1 Summary of the Relationship Between the Size and Percent Collapse of the Inferior Vena Cava and Central Venous Pressure

<table>
<thead>
<tr>
<th>IVC SIZE</th>

</tbody>
</table>

IVC, Inferior vena cava.

No set “normal” definition of the IVC has be established. Rather, both its size and percent collapse are situated on a spectrum, depending on the patient’s overall intravascular fluid status (Videos 3 and 4). Table 9.1 summarizes the relationship between IVC size and percent collapse with respiration correlated with CVP. These findings are applicable to trauma patients when attempting to establish their overall stability. A patient with a finding of low CVP following blunt abdominal trauma may cause the EP to be more aggressive in resuscitation or more cautious in delaying definitive management.

Video 1 Video of the interface between the visceral and parietal pleura demonstrating the “slide sign.”
Video 2 Video of the interface between the visceral and parietal pleura showing lack of movement (lack of a “slide sign”), which is consistent with pneumothorax.
Video 3 Video of the IVC before fluid resuscitation. The overall size of the IVC is small and there is nearly complete collapse with respiration.
Video 4 Video of the IVC after fluid resuscitation. The IVC now appears larger and does not collapse with respiration.

Procedural Sedation

Steven A. Godwin and Beranton Whisenant

KEY POINTS

- Procedural sedation refers to the technique of administering sedatives or dissociative agents with or without analgesics to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function.1,2
- Procedural sedation with analgesia in the emergency department is generally intended to create a depressed level of consciousness that allows the patient to maintain control of the airway and oxygenation without continuous assistance.
- Patients must be assessed before sedation to proactively identify potential difficulties associated with disease states and airway maintenance.
- When drugs are used in combination, their effects are more than additive, and this can be beneficial or can potentiate respiratory depression and cardiovascular instability.
- In patients with liver disease, the metabolism of drugs is altered in many ways and it is difficult to predict effects.
- In patients with a recent history of opiate and benzodiazepine overuse, propofol may offer advantages over other agents.

DEFINITIONS

Procedural sedation, not including dissociative agents, represents a continuum of sedation ranging across defined levels of consciousness. These varying degrees of awareness have been termed minimal sedation (anxiolysis), moderate sedation, deep sedation, and general anesthesia. See Table 10.1 for general definitions as defined by the Joint Commission. Because patients can move from one state or level of awareness to another without warning, serial assessment and close hemodynamic monitoring are advised.

INDICATIONS FOR PROCEDURAL SEDATION AND ANALGESIA IN THE EMERGENCY DEPARTMENT

Patients often arrive at the emergency department (ED) with acute injuries or disorders that require timely intervention to reduce both the physical and the psychologic effects of pain, anxiety, disability, and life-threatening complications. Common indications that may require procedural sedation are listed in Box 10.1.

PATIENT MONITORING

Because individual patient responses to sedatives and analgesics often vary, constant monitoring is essential to identify subtle changes in respiratory effort and hemodynamics. American College of Emergency Physician guidelines recommend that patients selected for procedural sedation and analgesia (PSA) undergo continuous cardiac monitoring, continuous pulse oximetry, and documented blood pressure checks every 5 minutes during the procedure and in the postprocedural period.2 Box 10.2 provides a list of objective physiologic parameters recommended for safe bedside monitoring. In addition, see Table 10.2 for the six-point Ramsay sedation scale, which was initially validated in intensive care units for the assessment of sedation depth and later modified to correlate with the Joint Commission definitions of sedation.

CAPNOMETRY (END-TIDAL CARBON DIOXIDE MONITORING)

Many PSA agents decrease tidal volume and the respiratory rate, thereby creating the potential for hypoventilation and apnea. In the majority of patients, pulse oximetry readings correlate well with arterial O2 saturation values. Unfortunately, oximetry is ineffective in the early detection of hyperventilation-induced hypercapnia, particularly if patients are receiving supplemental oxygen. Growing evidence for the routine use of continuous capnography during procedural sedation has led to its increased clinical use in an attempt to identify hypoventilation and avoid unrecognized periods of apnea.3 This monitoring technology may have its greatest benefit in patients whose ventilation status cannot be visualized (e.g., covered with a sterile sheet). Although clear evidence demonstrating differences in clinical outcomes with its use is not yet available, end-tidal CO2 monitoring is probably useful in providing an added level of safety when performing PSA.

PULSE OXIMETRY

Pulse oximetry readings may be misleading for a variety of reasons. The emergency physician must be aware of the pitfalls of this modality to correctly address changes in oxygenation (Table 10.3).3,4

MONITORING DEPTH OF SEDATION

Bispectral Index Monitoring

Electroencephalographic (EEG) bispectral index monitoring has been studied for use in the ED as a means of avoiding hypercapnia and hypoxic events and to objectively determine the depth of sedation during PSA. The bispectral index is a
statistical numeric value based on bispectral processing of the last 15 to 30 seconds of the harmonic and phase relationship of the frontal lobe EEG data. A score of 90 to 100 represents an awake state; 70 to 80, a moderate sedation state; 60 to 70, a deep sedation state; 40, general anesthesia; and 0, consistent with brain death. These scores can vary with the PSA used and in individual patients. The use of combination PSA agents makes titrating to a predefined bispectral index value difficult because of the synergistic effect of the agents. Evidence is insufficient to recommend the routine use of such monitoring in the ED.

### PREPROCEDURAL CONSIDERATIONS AND RISK ASSESSMENT

The clinician must obtain and document a complete history and physical examination for a patient when administering sedative medications. This step is critical in determining whether the patient is an appropriate candidate for PSA.

The goal of PSA is to effectively alleviate the patient’s anxiety, pain, and discomfort to the degree that best facilitates the safe performance of both painful and nonpainful procedures. PSA represents a dynamic continuum, with patients moving from one level of consciousness to the next without any clear point of transition. The predefined level of sedation should be determined on the basis of the patient’s acute disease state, the nature and duration of the therapeutic intervention being planned, and sedation and analgesia goals such as pain control, anxiolysis, and amnesia. In the ED the preferred method of administration for most PSA agents is often intravenous. Some agents, including intramuscular ketamine and inhalational sedation with nitrous oxide, are equally effective when delivered by experienced personnel in the appropriate setting.
GENERAL CONSIDERATIONS

- History: past medical history, anesthesia history, medications, allergies, review of systems, time of last meal
- Physical examination: vital signs (blood pressure, pulse rate, respiratory rate), pulse oximetry, airway assessment, cardiopulmonary and neurologic examinations
- Weighing risks against the benefits of performing PSA
- Urgency of performing PSA

RISK ASSESSMENT

Fasting Considerations
No compelling evidence is available to support fasting in the emergency setting for either children or adults. The emergency physician may consider a patient’s history of recent oral

Airway Evaluation
Assessment of the patient for potentially difficult bag-mask ventilation because of facial, oral, or neck anomalies is important before administration of PSA. Use of the mnemonics MOANS and LEMONS has been described as an aid in identifying anatomic and clinical features that may pose potential difficulties in airway management should bag-mask ventilation or intubation become necessary (Box 10.3).8

Set route and goals for sedation

Fig. 10.1 Algorithm for evaluation before sedation. ASA, American Society of Anesthesiologists [score]; OR, operating room.
BOX 10.3 Use of the Mnemonics MOANS and LEMON for Preprocedural Airway Assessment for a Difficult Airway

MOANS: Difficult Bag-Mask Ventilation
M: Mask seal—bushy beards, distorted lower facial contour
O: Obesity-obstruction—morbidly obese patients (because of increased redundant upper airway tissue) and patients with disorders that obstruct the upper airway
A: Age older than 55 years because of decreased muscular tone of the upper airway
N: No teeth, which creates difficulty in achieving an adequate mask seal
S: Stiff—patients with stiff noncompliant lungs, such as those with COPD, asthma, CHF, and pulmonary fibrosis

LEMON: Difficult Intubations
L: Look externally for physical features that may make intubation difficult—small mandible, large teeth, large tongue, short neck
E: Evaluate with the 3-3-2 rule:
  - For mouth opening, 5 cm or at least 3 (patient’s) fingerbreadths
  - Thyromental distance of 5 cm or at least 3 fingerbreadths
  - 2 fingerbreadths from the hyoid to the thyroid cartilage for evaluation of the position of the larynx in relation to the base of the tongue
M: Mallampati score—ability to visualize the posterior oropharynx with opening of the mouth
O: Obstruction—upper airway obstruction, stridor, odynophagia, and dysphagia
N: Neck mobility—immobilization because of cervical trauma, arthropathies

CHF, Congestive heart failure; COPD, chronic obstructive pulmonary disease.

BOX 10.4 Reversal Agents for Procedural Sedation and Analgesia (PSA)

Naloxone (Narcan)
Opioid antagonist that is used for oversedation and respiratory depression with opioids:
  - For partial reversal of oversedation of a PSA opioid agent, a dose of 0.1 to 0.4 mg can be used.
  - For complete reversal of sedation, 2 mg should be given intravenously.
  - Following reversal with naloxone, the patient should be observed for 90 minutes because of the risk for resedation.

Flumazenil
Reversal agent for benzodiazepine-induced oversedation and hypoventilation:
  - Use 1 mg for complete reversal of PSA with midazolam.
  - It has an onset of action of 1 to 2 minutes with a duration of 45 minutes.
  - Caution should be used in patients who are long-term users of benzodiazepines because of the risk for acute withdrawal.

- Lack of manipulation of the airway
- Depth of consciousness not meeting the level of general anesthesia

PHARMACODYNAMICS AND PHARMACOKINETICS OF COMMON AGENTS

In view of the array of procedures requiring PSA in the ED and the varied underlying clinical disorders, an understanding of the pharmacology of individual agents is important. Such knowledge allows the provider to tailor sedation and analgesia to meet individual patients’ needs. A number of agents are well suited to the ED environment because of their rapid onset of action, brief recovery period, and minimal untoward effects. It is difficult for a single agent to meet all the sedative and analgesic goals of an individual patient, and a combination of drugs is sometimes used. Table 10.4 details the pharmacology of individual PSA agents,9-15 and Table 10.5 details the drug effects of commonly used combination pediatric regimens.16,17 A list of reversal agents for PSA can be found in Box 10.4.

**Resuscitation in Pregnancy**

Elizabeth M. Datner and Susan B. Promes

---

**KEY POINTS**

- Displace the gravid uterus off the great vessels either manually or with a left lateral tilt to avoid aortocaval compression.
- Gain intravenous access above the diaphragm.
- Preoxygenate with 100% oxygen before intubation in anticipation of a more rapid onset of hypoxemia.
- In a pregnant woman, hands for cardiopulmonary resuscitation, chest tubes, and defibrillator paddles should be placed higher on the chest wall.
- Cardioversion and defibrillation will not harm the fetus.
- When the uterus is palpable above the umbilicus and the mother is in cardiac arrest, perform cesarean section immediately.
- Continue cardiopulmonary resuscitation during and after perimortem cesarean section and consider therapeutic hypothermia in a comatose patient with return of spontaneous circulation.
- For an Rh-negative woman who has vaginal bleeding after trauma, administer Rh immunoglobulin (RhGAM): a 50-mcg dose in the first trimester and a 300-mcg dose in the second or third trimester.
- In any pregnant woman at more than 24 weeks’ gestation who suffers trauma to the abdomen, fetal monitoring should be initiated as soon as possible and be maintained for 4 to 6 hours.

---

**SCOPE**

Resuscitation of a pregnant woman is an infrequent event. Cardiac arrest statistics are difficult to quantify, but cardiac arrest reportedly occurs in roughly 1 in 30,000 near-term pregnancies. More recent data suggest an increase in maternal mortality from cardiac arrest, with frequency rates of 1 in 20,000. In the event of cardiac arrest in a pregnant woman, two lives must be resuscitated. Quick, decisive management is paramount for the livelihood of the mother and her unborn child. Knowing exactly what to do and acting quickly ensure the best possible outcome for the mother and her unborn child.

**ANATOMY AND PHYSIOLOGY**

What are generally considered abnormal vital signs in non-pregnant people may actually be within the normal range for a pregnant woman. In gravid females, the heart rate and respiratory rate are increased. In the second trimester, blood pressure is decreased by 5 to 15 mm Hg, but it returns to normal near term. Hypoxemia occurs earlier in pregnant patients because of diminished reserve and buffering capacity. Pregnant patients have a slight respiratory alkalosis—PCO2 of 30 mm Hg and pH of 7.43—that must be taken into account when interpreting arterial blood gas values. Central venous pressure decreases in pregnancy to a third-trimester value of 4 mm Hg.

A pregnant woman has less respiratory reserve and greater oxygen requirements. The gravid uterus pushes up on the diaphragm, which results in reduced functional residual capacity. Minute ventilation and tidal volume rise, as does maternal oxygen consumption. The basal metabolic rate increases during pregnancy. The greater oxygen demands of the unborn child significantly alter the mother’s respiratory physiology, and the mother hyperventilates to meet the demands of the fetus. A pregnant patient at baseline is in a state of compensatory respiratory alkalosis because of excessive secretion of bicarbonate. A pregnant woman’s ability to compensate for acidosis is impaired. Other physiologic changes that may affect resuscitation are airway edema and friability, reduced chest compliance, and higher risk for regurgitation and aspiration.

As the uterus grows, it moves from the pelvis into the abdominal cavity, which pushes the contents of the abdominal cavity up toward the chest. In late pregnancy, the gravid uterus compresses the aorta and inferior vena cava and limits venous return to the heart. Stroke volume is decreased when a near-term pregnant woman is lying on her back and increased when the uterus is moved away from the great vessels. A woman in the second or third trimester of pregnancy should be placed in the left lateral tilt position, or the uterus should be manually displaced to the left to optimize cardiac output and venous return. During late pregnancy, cardiac output is increased. Pulmonary capillary wedge pressure remains unchanged, as does the ejection fraction.

Electrocardiographic changes, including left axis deviation secondary to the diaphragm moving cephalad and changing the position of the heart, are also present during pregnancy. Q waves are present in leads III and aVF, and flattened or inverted T waves are seen in lead III.

During pregnancy blood volume increases, which causes a dilution anemia. The average hematocrit value is 32% to 34%. White blood cell counts are higher than normal and platelet counts are lower in pregnancy. Blood urea nitrogen and serum creatinine values are lower than normal, as are cortisol values. The erythrocyte sedimentation rate is increased. Albumin and total protein levels are decreased. Fibrinogen levels double in pregnancy, so a patient with disseminated intravascular coagulation could have a normal fibrinogen level.

Pregnancy-related changes can be seen on radiographic studies. A chest radiograph of a pregnant woman shows an
increased anteroposterior diameter, mild cephalization of the pulmonary vasculature, cardiomegaly, and a slightly widened mediastinum. Widening of the sacroiliac joints and pubic symphysis are apparent on imaging of the pelvis. Radiography should not be avoided in a pregnant woman because of concerns about radiation exposure of the fetus, which can simply be shielded. Ultrasonography can be used at the bedside to identify fluid in the abdomen, pelvis, and pericardium and to evaluate fetal activity and heart rate. Fetal well-being is closely linked to the well-being of the mother, so all studies indicated for diagnosis and treatment of the mother should be performed.

**DIFFERENTIAL DIAGNOSIS**

Pregnant women are generally young and healthy. The rare cardiac arrest in a gravid female may be due to venous thromboembolism, severe pregnancy-induced hypertension, amniotic fluid embolism, or hemorrhage. In addition to such pregnancy-related problems, pregnant women are not exempt from common conditions that affect the general population. Trauma and sepsis may lead to cardipulmonary failure and the need for maternal resuscitation. **Box 11.1** lists key etiologic factors leading to cardiac arrest in pregnant patients.

**HEMORRHAGE**

During routine vaginal delivery, the average blood loss is 500 mL. Excessive blood loss or postpartum hemorrhage complicates 4% of vaginal deliveries. Common causes of hemorrhage around the time of delivery are uterine atony (excessive bleeding with a large relaxed uterus after delivery), vaginal or cervical tears, retained fragments of placenta, placenta previa, placenta accreta, and uterine rupture. Hereditary abnormalities in blood clotting may cause hemorrhage, so inquiries about excessive bleeding, known disorders, and family history are relevant in a patient with excessive bleeding.

**NONHEMORRHAGIC SHOCK**

Causes of nonhemorrhagic obstetric shock—pulmonary embolism, amniotic fluid embolism, acute uterine inversion, and sepsis—are uncommon but are responsible for the majority of maternal deaths in the developed world. These conditions must be diagnosed and treated expeditiously. Patients in whom pulmonary embolism is suspected should be administered heparin and then undergo diagnostic imaging. Although fibrinolytic agents are contraindicated in pregnancy, they have been used successfully in patients with life-threatening pulmonary embolism and ischemic stroke. Treatment of amniotic fluid embolism is supportive, the goals being to maintain maternal oxygenation and support blood pressure. Some case reports describe success with the use of cardiopulmonary bypass to treat women suffering from amniotic fluid embolism.

Acute uterine inversion can also cause shock. Cardiovascular collapse complicates approximately half the cases of acute uterine inversion. Classically, the extent of the shock is out of proportion to the blood loss noted. One theory to explain this observation is that a parasympathetic reflex causes neurogenic shock from stretching of the broad ligament or compression of the ovaries (or both) as they are drawn together. Uterine replacement combined with vigorous fluid resuscitation, including blood transfusion as required, should reverse the hypotension.

**TRAUMA**

Traumatic injuries occur commonly in pregnancy and are the leading cause of maternal death; they account for more than 46% of cases. Motor vehicle crashes, assaults, and falls are the most common causes of injuries. Pregnant women are at increased risk for domestic violence, and this possibility should be considered and the police notified when warranted.

Fetal outcome is affected when the mother becomes hypertensive or acidotic as a result of major injury. Maternal vital signs and physical symptoms do not predict fetal distress in women with minor trauma. Only cardiotocographic monitoring for a minimum of 4 to 6 hours is useful in predicting fetal outcome. After even apparently minor falls women should undergo fetal monitoring.

In pregnant women suffering blunt trauma, most fetal deaths occur as a result of placental abruption. Classic symptoms are abdominal cramps, vaginal bleeding, uterine tenderness, and hypovolemia (several liters of blood can accumulate in the uterus). None of these findings are sensitive and cannot be relied on, so monitoring is required.

**DIAGNOSTIC TESTING**

**INTERVENTIONS AND PROCEDURES**

A fundamental principle in treating pregnant women is that fetal well-being depends on maternal well-being. As with all patients in the emergency department (ED), resuscitation...
starts with the ABCs (airway, breathing, and circulation). One hundred percent oxygen should be administered to the mother early. Hypoxia should be treated aggressively in this patient population because when the mother is hypoxic, oxygen is shunted away from the fetus. Additionally, preoxygenation is important because apnea results in more rapid hypoxia in the setting of pregnancy. Rapid-sequence induction with precautions for aspiration is essential before intubation. Aggressive volume resuscitation, administration of vaspressors if needed, and close attention to the patient’s body position are all very important in the treatment of hypotension in a pregnant patient. Fetal heart monitoring and, ideally, cardiotocographic monitoring should be initiated as soon as possible for patients in the second or third trimester of pregnancy.¹⁸

A commercially produced wedge called a Cardiff wedge is available to aid in the resuscitation of pregnant women. It can be placed under the woman’s right side to support her back while she lies in the preferred left lateral tilt position. In the absence of a wedge, a human wedge can be used, with the patient being tilted on the bent knees of a kneeling rescuer. Pillows, towel rolls, and blanket rolls are readily available in EDs and accomplish the same purpose of angling the woman’s back 30 to 45 degrees from the floor (Fig. 11.1). If for some reason the patient must lie on her back, as in the case for adequate cardiopulmonary resuscitation (CPR), a member of the health care team should manually displace the uterus to the left so that it does not rest on the great vessels.

The American Heart Association (AHA) basic life support guidelines should be followed with two modifications:

- Move the uterus off the great vessels.
- Adjust the hand position for CPR cephalad to account for displacement of the thoracic contents by the gravid uterus.

The AHA advanced cardiac life support (ACLS) guidelines for medications, intubation, and defibrillation for patients in cardiac arrest should be followed for gravid females with one simple exception—a change in placement of the defibrillation paddles and pads:

- Place one paddle below the right clavicle in the midclavicular line.
- Position the second paddle outside the normal cardiac apex so that it avoids breast tissue.⁷

Defibrillation energy requirements remain the same (Fig. 11.2).³ Defibrillation will not harm the fetus. ACLS medications should be used as needed. It is reasonable to remove external or internal fetal monitoring devices during electrical shock of the mother because of the possibility of creating an electrical arc to the monitoring equipment, but this is unlikely with the electrical current applied to the maternal thorax. Box 11.2 lists the U.S. Food and Drug Administration categories for the various ACLS drug options during pregnancy.

In pregnant patients with trauma who are in need of a thoracostomy, the chest tube must be placed one or two intercostal spaces higher than normal to avoid diaphragmatic injury. An open supraumbilical approach should be used for diagnostic peritoneal lavage in a pregnant patient, with the gravid uterus palpable on abdominal examination.

If return of spontaneous circulation (ROSC) is achieved, effort must be directed at further hemodynamic stabilization. Post–cardiac arrest therapeutic hypothermia has been successful in the setting of early pregnancy and is recommended as for nonpregnant patients.¹⁶ In a comatose post–cardiac arrest patient with ROSC, the patient should be cooled as soon as possible and within 4 to 6 hours to 32°C to 34.8°C for a 12-to 24-hour duration to gain the best possible neurologic outcome. If a perimortem cesarean section has not been performed because of gestational age less than 24 weeks, fetal monitoring should be performed during hypothermia in anticipation of bradycardia.¹¹

**IMAGING**

Ultrasonography is an important method for assessment of both the mother and fetus, but additional radiographic studies are often required. Shielding can ensure that exposure even with maternal head and chest computed tomography (CT) can be kept below the 1-rad (1000-millirad) limit. Intrauterine exposure to 10 rad (10,000 millirad) produces a small increase in childhood cancer; exposure to 15 rad creates a risk for mental retardation, childhood cancer, and a small head. A head or chest radiograph delivers less than 1 millirad to the shielded gravid uterus. A lumbar spine, hip, or kidneys-bladder radiograph delivers more than 200 millirad. A CT scan of the head delivers less than 50 millirad to the shielded uterus, and a chest CT scan provides an exposure of less than 1000 millirad. In sum, important radiographic studies of the head, neck, and chest can safely proceed if the uterus is shielded.

**FETOMATERNAL TRANSFUSION**

After the 12th week of pregnancy, when the uterus rises above the pelvic rim and becomes susceptible to trauma, fetal blood can theoretically cross into the maternal circulation after significant trauma. A 50-mcg dose of Rh immunoglobulin (RhoGAM) is used when the mother is Rh negative. During the second and third trimesters a 300-mcg dose is administered, which protects against 30 mL of fetomaternal hemorrhage. A 16-week fetus has about a 30-mL volume of blood, so the entire blood volume is covered by the 300-mcg dose.

Pregnant patients in the second or third trimester who suffer major traumatic injury could theoretically have fetomaternal...
transfusion that exceeds the coverage provided by the 300-mcg dose. This situation is rare and occurs in less than 1% of pregnant patients after trauma. In patients with major trauma and advanced pregnancy, the Kleihauer-Betke test should be considered, especially when significant vaginal bleeding is present. Rh immunoglobulin is effective when administered within 72 hours, so the test does not have to be performed in the ED.

**PERIMORTEM CESAREAN SECTION**

The two goals of perimortem cesarean section are to improve the unstable hemodynamics of the mother and minimize morbidity and mortality in the child. If resuscitative efforts, including ACLS algorithms and alleviation of aortocaval compression, fail to improve maternal hemodynamics, perimortem cesarean section must be considered. The likelihood that perimortem cesarean section will result in a living and neurologically normal infant is related to the interval between onset of maternal cardiac arrest and delivery of the infant.12,13

The gestational age of the neonate is also critical. If cesarean section is performed in the ED, it should be done rapidly. Time is of the essence. Fetal viability outside the uterus is best beyond 24 weeks’ gestation, but it is not always possible to know the exact gestational age in the ED. On the basis of case reports, it is recommended that cesarean section be performed in the ED if the gestational age is believed to be more than

---

**Fig. 11.2 Algorithm for resuscitation of a pregnant patient.** CPR, Cardiopulmonary resuscitation.
20 weeks. At this stage of pregnancy, the fundus is likely to be palpable at or above the level of the umbilicus.

The child should be delivered within 5 minutes of maternal cardiac arrest, so the procedure should be initiated within 4 minutes of failed CPR of the mother. The procedure is summarized in Box 11.3. Maternal CPR should be maintained throughout the procedure to optimize blood flow to the uterus and the mother and should be continued after cesarean section. Once delivery is accomplished, ED personnel should be prepared to resuscitate the neonate. It is important to note that published and anecdotal reports describe return of maternal blood pressure and maternal survival after perimortem cesarean section. Successful resuscitation of a pregnant woman and her unborn child requires a coordinated team approach.

**CONCLUSION**

In the setting of resuscitation, a pregnant woman poses challenges given the physiologic and anatomic changes associated with pregnancy. Remembering these normal adjustments that occur in gravid women is critical. Aortocaval compression must be avoided during resuscitation of a pregnant woman. Appropriately diagnosing the cause of the patient’s medical problem while being mindful of the ABCs of resuscitation is a must. Thankfully, cardiac arrest is an uncommon event in pregnant women. When it occurs later in pregnancy, perimortem cesarean section may improve the outcome of the infant and mother if performed in a timely manner. As with all resuscitations, a team effort is mandatory, but possibly even more so in this setting because the emergency practitioner is caring for two patients whose lives are very tenuous and time is of the essence.

Neonatal Cardiopulmonary Resuscitation

Katherine Bakes and Ghazala Q. Sharieff

KEY POINTS

• In newborn resuscitation, simultaneous auscultative assessment of the heart rate and respirations should precede more advanced interventions.

• Because visual determination has been found to be unreliable, pulse oximetry with the minimal oxygen supplementation necessary to maintain adequate oxygen saturation should be used to assess newborns.

• Endotracheal intubation should be considered for tracheal suctioning of meconium, heart rates below 100 beats/min that do not respond to initial bag-valve-mask ventilation, prolonged bag-valve-mask ventilation or chest compressions, administration of medications, and other special considerations such as congenital diaphragmatic hernia and extremely low birth weight.

• If the heart rate remains below 60 beats/min despite respiratory support, chest compressions should be performed at a rate of at least 100 compressions per minute via the two-finger or chest-encircling technique. The chest-encircling technique is preferred for chest compressions. The ratio of compressions to ventilations should be 3:1, with 90 compressions and 30 breaths to achieve approximately 120 events per minute to maximize ventilation at an achievable rate. Each event will be allotted approximately \( \frac{1}{2} \) second, with exhalation occurring during the first compression after each ventilation.

PERSPECTIVE

Approximately 10% of newborns require assistance after birth to achieve spontaneous breathing, and 1% need additional support. The likelihood of survival can be estimated from the gestational age and birth weight (Fig. 12.1).\(^1\)

SURVIVAL WITH COMORBID CONDITIONS

A 2001 study reviewing more than 700 neonatal intensive care unit admissions involving infants born at or before 25 weeks’ gestation found that survivors (63%) had a high incidence of chronic lung disease (51%), high-grade retinopathy of prematurity (32%), intraventricular hemorrhage (44%), nosocomial infection (38%), and necrotizing enterocolitis (11%).\(^2\)

In this same study, only 23% of survivors had no major morbidity, defined as chronic lung disease, necrotizing enterocolitis, at least grade 3 intraventricular hemorrhage, or at least grade 3 retinopathy of prematurity.

ANATOMY

Anatomic considerations for the neonatal airway are similar to those discussed for pediatric patients (see Chapter 13), with the exception that the structures are even smaller and more anterior and superior, thus making visualization of the vocal cords an even greater challenge.

The neonatal chest wall is very flexible and can be notably distorted if vigorous inspiratory efforts are made; such distortion results in inadequate lung expansion and the potential need for positive pressure ventilatory support, particularly in premature infants who lack adequate surfactant production.

PRESENTING SIGNS AND SYMPTOMS

“Yes” answers to the following three questions identify babies who do not require support after birth but can be dried, covered, and kept with the mother if desired.\(^3\)

• Was the baby born after a full-term gestation?

• Is the baby breathing or crying?

• Does the baby have good muscle tone?

INTERVENTIONS AND PROCEDURES: RESUSCITATION STEPS

Figure 12.2 lists the steps in neonatal resuscitation.

If the answer to any of the three questions just listed is “no,” the infant should receive the following in sequence, with 60 seconds allotted for completing and beginning ventilation if needed:

• Stabilization (warm, clear the airway, dry, stimulate)

• Ventilation

• Chest compressions

• Epinephrine, volume expansion, or both
Fig. 12.1 Percent mortality in infants who are small for gestational age (SGA) versus infants who are appropriate for gestational age (AGA) according to gestational age at birth. The mortality rate of SGA infants was significantly higher than that of AGA infants in the 25th gestational week (P = .015) and from 26 to 29 weeks of gestation (P < .01). (From Regev RH, Lusky A, Doffin T, et al. Excess mortality and morbidity among small-for-gestational-age premature infants: a population-based study. J Pediatr 2003;143:186-91.)

Apgar scores are measured at 1 minute and 5 minutes after delivery. These scores are used to (1) predict which infants will require resuscitation and (2) identify infants who are at higher risk for neonatal mortality. A score of 7 or higher is reassuring (Table 12.1).

AIRWAY
The American Heart Association (AHA) no longer recommends routine intrapartum oropharyngeal and nasopharyngeal suctioning because it has been shown to be associated with cardiopulmonary complications in healthy neonates. Oropharyngeal and nasopharyngeal suctioning should be reserved for newborns with obvious upper airway obstruction and associated respiratory distress.3,4

Meconium-stained amniotic fluid occurs in up to 20% of deliveries, and as many as 9% of infants with meconium-stained amniotic fluid experience meconium aspiration syndrome (MAS), which carries a modern-day mortality rate of up to 40%.4

MAS occurs when the fetus aspirates meconium before or during birth, which leads to obstruction of the airways, atelectasis, severe hypoxia, inflammation, acidosis, and infection.5 The AHA guidelines regarding the management of a newborn with potential meconium aspiration make no distinction between thin and thick meconium because both have shown to lead to MAS.

In the absence of randomized controlled trials on routine tracheal suctioning of depressed infants born through meconium-stained amniotic fluid, the 2005 newborn resuscitation guidelines have not changed significantly. Thus, a nonvigorous newborn with meconium-stained amniotic fluid should not be suctioned on the mother’s perineum. Avoiding such suctioning prevents undue stimulation, which would lead to breathing and aspiration of meconium before endotracheal suctioning.6 Endotracheal intubation (ETI) and suctioning of meconium should be performed with a 10 French (F) to 14 F suction catheter and a meconium aspirator attached to an endotracheal tube. If intubation attempts are prolonged, bag-mask ventilation should not be delayed, especially when bradycardia is present.4

A vigorous neonate born with meconium-stained amniotic fluid does not require endotracheal suctioning for any level of meconium staining. Endotracheal suctioning has shown no benefit in this setting because the meconium has already caused irreversible damage to the lower airways. Vigorous is defined as having strong respiratory effort, good muscle tone, and a heart rate higher than 100 beats/min.

BREATHING
Methods to stimulate breathing in neonatal resuscitation are as follows:

- Rubbing the back/spine
- Flicking the soles of the feet
- Vigorously drying the skin
Fig. 12.2 Newborn resuscitation algorithm. CPAP, Continuous positive airway pressure; ET, endotracheal; HR, heart rate; IV, intravenous; PPV, positive pressure ventilation. (Modified from Kattwinkel J, Perlman JM, Aziz K, et al. Part 15: neonatal resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 2010;122:S909-19.)

If these measures are not stimulating an adequate change in heart rate, oxygenation, or activity, blow-by oxygen (blowing or wafting oxygen) should be administered.

Positive pressure ventilation (PPV) via a bag-valve-mask device at a rate of 40 to 60 breaths/min is indicated for the following situations3,4:

- The infant is apneic or gasping after warming, stimulation, and administration of blow-by oxygen.
- The heart rate remains lower than 100 beats/min after the preceding methods have been applied.
- The infant has persistent hypoxia.
Following pulse oximetry and titration of oxygen as needed, a term infant undergoing PPV should be started on room air and a preterm infant on a blend of air and oxygen. Starting PPV with 100% oxygen should be avoided because it is potentially harmful at the cellular level.

In a term infant, an initial inflation pressure of 20 cm H₂O may be sufficient and could be increased to 30 to 40 cm H₂O as needed to achieve adequate movement of the chest wall and elevation of the heart rate; inflation pressures in preterm infants should be 20 to 25 cm H₂O.

In the absence of meconium-stained amniotic fluid, laryngeal mask airways may be used in a newborn weighing more than 2000 g or delivered at more than 34 weeks’ gestation and requiring assisted ventilation, but not chest compressions.⁸

Continuous positive airway pressure (CPAP) delivered via face mask immediately after delivery may be used in a neonate with respiratory effort but significant distress.⁹ Devices that provide some level of CPAP include standard self-inflating bags, flow-inflating bags, and predetermined CPAP devices such as the Neopuff Infant Resuscitator (Fisher and Paykel, Auckland, NZ). Benefits of CPAP include reduced need for intubation, diminished work of breathing, reduced incidence of apnea, decreased inspiratory resistance, and improved oxygenation. Drawbacks include an increased risk for pneumothorax and those related to the risk associated with overdistention, which can result in reduced pulmonary perfusion, diminished cardiac output, and ultimately, ventilation-perfusion mismatch. The current AHA recommendations allow either CPAP or intubation to be used in infants requiring ventilatory support.⁶

Guidelines for ETI in neonatal resuscitation are as follows³⁴:

- Tracheal suctioning is needed for nonvigorously newborns with meconium-stained amniotic fluid.
- Bag-valve-mask ventilation is prolonged or ineffective.
- Chest compressions are prolonged.
- Administration of medications by endotracheal tube is desired.
- Special considerations include conditions such as congenital diaphragmatic hernia or extremely low birth weight.

**CIRCULATION**

It is recommended that assessment of the heart rate be performed via auscultation at the anterior surface of the chest. However, if palpation is used, the umbilical pulse should be used while recognizing that this method may underestimate the heart rate. If the heart rate remains below 60 beats/min despite respiratory support, chest compressions (on the lower third of the sternum and at a depth of one third the diameter of the chest) should be performed at a rate of at least 100 per minute with the two-finger or the preferred chest-encircling technique (Fig. 12.3). At this point, the ratio of chest compressions to breaths should be 3:1 unless a cardiac cause is suspected, in which case a 15:2 ratio should be considered.

If an intravenous (IV) line cannot be placed, an umbilical catheter can be used. The umbilical vein (UV) may be used for blood sampling, fluid or drug infusion, and monitoring of blood pressure and central venous pressure. Anatomically, there are typically two umbilical arteries (UAs) and one UV. The UV is usually in the 12-o’clock position and has a thinner wall and wider lumen than the UAs. The UV is often described as resembling a “smiley face.” In emergency situations the UV is the preferred vessel to access because the UAs are often tortuous and difficult to cannulate. The umbilicus should be prepared with a bactericidal solution and draped, and a silk suture should be placed around the base of the umbilical stump. The distal end of the stump is cut off, and the vessels are occluded to prevent blood loss. A 3.5 to 5.0 F catheter is flushed with saline and inserted into the lumen of the desired vessel. The UV catheter should be advanced just to the point where good blood return is obtained (Fig. 12.4). Plain radiographs should be taken to confirm placement. Complications of umbilical catheters include hemorrhage, infection, air embolism, and perforation of a blood vessel.

Umbilical vein catheterization can reasonably be attempted up to 1 week after delivery, although the likelihood of cord patency diminishes with time.
MAINTENANCE OF TEMPERATURE

For a well term infant, temperature can be maintained with standard drying followed by swaddling and placement under warming lights or on the mother’s warm skin. Very-low-birth-weight infants (<1500 g) require additional warming techniques. The AHA guidelines recommend wrapping the newborn in “food-grade heat-resistant plastic wrapping” and placing the newborn under radiant heat.

Some evidence indicates that induced hypothermia (33.5°C to 34.5°C) may decrease the rate of death or disability (or both) in asphyxiated newborns. Using clearly defined protocols, infants born at greater than 36 weeks’ gestation with suspected severe hypoxic-ischemic encephalopathy should be treated with therapeutic hypothermia within 6 hours. If these protocols are not in place, at the very least, hyperthermia should be strictly avoided.

RESUSCITATION MEDICATIONS AND VOLUME REPLACEMENT

The need for resuscitation medications is rare in the delivery room. Bradycardia is usually secondary to a primary respiratory cause. However, in the rare instance in which ventilatory support does not reverse the bradycardia, standard-dose IV epinephrine at 0.01 to 0.03 mg/kg of a 1:10,000 solution should be administered. Although IV administration is preferred, a higher dose of epinephrine, 0.05 to 0.1 mg/kg of a 1:10,000 solution, can be administered through the endotracheal tube until IV access has been established.

If volume replacement is necessary, isotonic crystalloid is recommended at 10 mL/kg, with repeated dosing as dictated by the clinical situation. Caution should be used when giving fluids because rapid newborn volume expansion has been associated with intraventricular hemorrhage (Tables 12.2 and 12.3). Glucose regulation is particularly important during the poststabilization period in an asphyxiated newborn, whose glycogen stores can be depleted rapidly. Although a target glucose level has not been established, a serum glucose level greater than 40 mg/dL should be maintained with the administration of 10% dextrose in water (D10W).

Naloxone administration should generally be avoided in the resuscitation of a newborn at the time of delivery; instead, one should concentrate on support of breathing and the circulation. Administration of naloxone to mothers with known opioid addiction can have adverse outcomes and is not recommended by the AHA.3

Bicarbonate is not routinely recommended in the acute resuscitation of a newborn because of studies showing deleterious effects, including depression of myocardial function, intracellular acidosis, reductions in cerebral blood flow, and risk for intracranial hemorrhage.11

Pediatric Resuscitation

Ghazala Q. Sharieff and Katherine Bakes

KEY POINTS

- Correct positioning is imperative for successful management of the anterior and cephalad pediatric airway.
- Outside the newborn period, use of a cuffed endotracheal tube in a child is acceptable.
- Children in full cardiorespiratory arrest who have an advanced airway should not receive more than 8 to 10 breaths per minute during resuscitation.
- “Push hard, push fast” with minimal interruptions between compressions is the recommendation for cardiopulmonary resuscitation.

EPIDEMIOLOGY

Cardiac arrest in children most commonly stems from respiratory pathology, with pneumonia, asthma, bronchiolitis, and aspiration accounting for the most common causes. In pediatric in-hospital and out-of-hospital arrests, only 5% to 15% of patients will have pulseless ventricular tachycardia (VT) or ventricular fibrillation (VF). Although survival rates after in-hospital arrest have increased from 9% in the 1980s to 27% in 2006, the survival rate after out-of-hospital arrest has remained relatively constant at 6%.

Results from studies of pediatric in-patient cardiac arrest have shown that patients with VF or pulseless VT have a 34% survival rate to discharge whereas patients with pulseless electrical activity have a 38% survival rate. The worst outcomes occur in children with asystole, with only 24% of these children surviving to hospital discharge. Infants and children with a pulse but poor perfusion and bradycardia who require cardiopulmonary resuscitation (CPR) have the best survival to discharge (64%), thus suggesting that early intervention to prevent full cardiopulmonary arrest portends the best outcomes.

BASIC PRINCIPLES OF CARDIOPULMONARY RESUSCITATION

Single-rescuer CPR providers should institute emergency medical service treatment after 1 minute of rescue breathing and compressions if the patient is younger than 8 years because the underlying cause is more likely to be respiratory than cardiac in this population. The American Heart Association (AHA) recommends “push hard and push fast” with compressions. Infants and children should have a compression rate of at least 100 per minute. In single-rescuer CPR, the compression-to-ventilation ratio should be 30:2. For health care providers or responders trained in CPR, the ratio is 15:2. In newborns, the compression-to-ventilation ratio should be 3:1. According to the pediatric advanced life support (PALS) guidelines, adequate compression depth is approximately one third to one half the anterior-posterior diameter of the patient’s chest—4 cm in infants and 5 cm in children. In infants, the two-thumb method is preferred over the finger method for compressions. For optimal compressions, full recoil of the chest should take place after each compression, with a firm surface behind the victim.

The effectiveness of CPR is best judged by the presence of a femoral pulse with corresponding chest compressions. Interruptions in compressions have been shown to decrease the rate of return to spontaneous circulation and should be limited to less than 10 seconds for interventions such as placement of an advanced airway or defibrillation. Rhythm checks should be performed every 2 minutes (every five cycles of CPR). Once an advanced airway is in place, compressions and breaths should be performed continuously without interruption. Because of rescuer fatigue and the importance of proper compressions, it is ideal for the person performing compressions to be rotated every 2 minutes.

Foreign body removal maneuvers consist of a sequence of five back blows and five chest thrusts for infants and the Heimlich maneuver for children (Fig. 13.1). Blind finger sweeps should not be performed in children because a partial obstruction can be turned into a full obstruction if the foreign body is pushed further into the airway. Because of the pliability of the esophageal wall, foreign bodies in the esophagus can impinge on the trachea and result in airway obstruction. If the foreign body cannot be removed with basic life support maneuvers and the patient decompensates, the clinician can attempt to remove any visible foreign body with Magill forceps. Intubation may be required, and it may be possible to push the foreign body into a mainstem bronchus, most commonly on the right side. If this maneuver fails and the patient cannot be intubated, the last resort is either needle cricothyrotomy or a surgical airway. In a stable patient, bronchoscopy with maintenance of the patient’s position of comfort is the treatment of choice.
AIRWAY MANAGEMENT

Airway management in children can be anxiety provoking; the same preparation guidelines outlined in Chapter 1 should be followed. Signs of respiratory failure include an increased or decreased respiratory rate, nasal flaring, grunting, retraction, cyanosis, apnea, or altered mental status. Hypoxia, compromised airway protection, altered mental status, and impending respiratory failure are common indications for pediatric airway intervention. Because most pediatric cardiac arrests are secondary to respiratory failure, early airway intervention is crucial.
ANATOMY

The pediatric airway differs significantly from the adult airway (Box 13.1), and some special techniques are helpful when intubating a child. An oral or nasal airway can assist in maintaining airway patency. Because of the large occiput in a young child, typically those younger than 1 year, a towel roll placed beneath the patient’s shoulders often improves airway alignment. To visualize the very anterior pediatric airway, the operator must look up during intubation and may need to squat or raise the bed for adequate viewing. To see the glottic opening, a straight blade is recommended to lift up an infant’s floppy omega-shaped epiglottis. Because of infants’ small mouths, an assistant may need to pull the baby’s cheek to the side to allow passage of the laryngoscope and endotracheal tube.1,2

*Timed intubation: When using nondepolarizing agents, it is not necessary to induce anesthesia in the patient immediately. This permits a timed intubation in which the nondepolarizing agent is administered first and subclinical muscle relaxation is begun. Approximately 15 seconds later the induction agent is administered. Both agents then therapeutically overlap at about 30 to 45 seconds after the beginning of the procedure, which results in good intubating conditions.

RAPID-SEQUENCE INTUBATION IN CHILDREN

The intubating time line and drugs of choice are listed in Tables 13.1 and 13.2. Postintubation assessment includes confirmation that the endotracheal tube is in correct position. First listen over the stomach and then over the axillae for breath sounds. A confirmatory device such as an end-tidal carbon dioxide monitor, a carbon dioxide chart (e.g., Pedi-Cap, which should change from purple to yellow with proper tube placement), or an esophageal detector should be used.3,4 A nasogastric or orogastric tube should also be placed as soon as possible because any amount of gastric distention can make ventilation and oxygenation of a child difficult. A rough rule of thumb for nasogastric and orogastric tube size is two times the endotracheal tube size.

IM, Intramuscularly; IV, intravenously.
endotracheal tubes, the dictum of using only uncuffed endotracheal tubes in children younger than 8 years has changed. It is not only acceptable but at times preferable (high peak pressure) to use a cuffed endotracheal tube in children. For an approximate guide to tube size, use $4 + (age + 4)$ for uncuffed tubes and $3.5 + (age + 4)$ for cuffed tubes. Cuff inflation pressure should be kept less than 20 to 25 cm H$_2$O. Cuffed endotracheal tubes are not recommended for use in neonates.$^{5,6}$

Table 13.4 summarizes the procedure for rapid-sequence intubation in children.

An incorrect endotracheal tube size can lead to an inability to ventilate if the tube is too small or result in airway trauma (e.g., subglottic edema) if the tube is too large. Easy formulas for estimating the depth of endotracheal tube placement are as follows:

$$3 \times \text{endotracheal tube size}; \text{for example, a } 4.0\text{-mm tube placed with the } 12\text{-cm mark at the gum line}$$

$$10 + \text{age in years} = \text{number of centimeters of the tube to the lips}$$

For premature infants, the following estimations of tube depth based on body weight are helpful:

$$\begin{align*}
1 \text{ kg}: & \ 7 \text{ cm} \\
2 \text{ kg}: & \ 8 \text{ cm} \\
3 \text{ kg}: & \ 9 \text{ cm} \\
4 \text{ kg}: & \ 10 \text{ cm}
\end{align*}$$

Approximate laryngoscope sizes are listed in Table 13.5. The Broselow-Luten resuscitation tape can also be used to select the weight-based appropriate size. It is important to remember that the actual blade size needed is determined by the individual patient’s weight, body habitus, and anatomic variability. Preparation is essential; having laryngoscope blades available that are one size smaller and one size larger than anticipated prevents costly delays.

Once endotracheal tube placement is confirmed, the tube must be secured. The endotracheal tube can be dislodged very easily, particularly in young infants with small tracheal widths.

### Box 13.2 Ways of Choosing Endotracheal Tube Size

1. Estimate size according to the patient’s age:
   - Newborns, 3.0 mm, or in large newborn, 3.5 mm
   - Up to 6 months, 3.5 to 4.0 mm
   - 1 year, 4.0 to 4.5 mm
   - Older than 1 year:
     - Uncuffed tube: $4 + (age ÷ 4)$
     - Cuffed tube: $3.5 + (age ÷ 4)$
   - Cuffed tubes should not be used in neonates

2. Use a length-based resuscitation tape, such as the Broselow-Luten

3. Estimate according to the patient’s finger:
   - The width of the child’s little fingernail is used to estimate the internal diameter of the endotracheal tube
   - The width of the child’s little finger is equal to the width of the whole endotracheal tube

---

### PHARMACOLOGIC AGENTS FOR RAPID-SEQUENCE INTUBATION IN CHILDREN

Potential combinations of agents for rapid-sequence intubation are listed in Table 13.3. Pretreatment with multiple agents is not recommended because placement of an advanced airway may be delayed. Atropine has recently been called into question for routine use in pediatric intubation, but it is recommended in infants younger than 1 year to avoid the bradycardia associated with airway manipulation in this population. The dose of atropine ranges from 0.01 to 0.02 mg/kg (minimum dose, 0.1 mg).

### PRINCIPLES OF ENDOTRACHEAL INTUBATION

Recommended endotracheal tube sizes are listed in Box 13.2. With the advent of high-volume, low-pressure cuffed
A cervical collar, even in the nontrauma setting, can minimize tube motion and dislodgement.

**BREATHING**

**Bag-Valve-Mask Ventilation**

Self-inflating, hand-squeezed resuscitators are commonly used in children because of the elasticity of the self-inflating bag, which allows independent refilling. Many of these bags have a pressure-limited pop-off valve, typically set at 30 to 35 cm H₂O to prevent barotrauma. Sometimes higher pressure is required, depending on the child’s pathophysiology. Correct mask sizing is vital for proper bag-valve-mask ventilation. The mask should fit snugly from the bridge of the nose to the cleft of the chin. A mask that is too large can place pressure on the eyes and cause vagal bradycardia. A mask that is too small will not allow adequate oxygenation and ventilation. The mask should be held with a “CE” grip—the holder’s thumb and index finger grip the mask and the third, fourth, and fifth fingers are placed on the angle of jaw. It is important to avoid pushing on the soft tissue below the mandible, which can cause airway obstruction.

The rate of bagged breaths per minute is best controlled by having the operator say “squeeze-release-release” as the patient is being ventilated. This practice helps decrease the rapid rate of ventilation and resultant adverse effects of over-inflation. Patients in full arrest with an advanced airway in place should not receive more than 8 to 10 breaths/min via mask airway (LMA) has the advantages of easy placement without the need for laryngoscopy and little cardiac effect during the insertion process. Disadvantages include the lack of airway protection from vomiting or aspiration of gastric contents, the requirement that the patient be unconscious or sedated for placement, and the fact that an LMA is not a definitive airway. Furthermore, in children less than 30 kg, higher ventilatory pressure may be required because the LMA can fold the epiglottis over and cause partial upper airway obstruction.

**Initial Ventilator Settings**

Initial ventilator settings are typically chosen through assessment of the height and weight of the patient and the underlying cause of the respiratory distress.

For children weighing less than 10 kg, a pressure-limited system should be used. The infant should be given sufficient oxygen to relieve cyanosis and maintain normal oxygen saturation (92% to 96%) or normal P₀₂ (60 to 90 mm Hg). The following are recommended initial ventilator settings:

- Rate: 20 to 60 breaths/min (goal PaCO₂, 35 to 45 mm Hg)
- Fraction of inspired oxygen (FI₀₂): 100% (wean slowly based on pulse oximetry)
- Positive end-expiratory pressure (PEEP): 3 to 5 cm H₂O
- Peak inspiratory pressure: 15 to 35 cm H₂O (or sufficient to produce discernible chest wall movement)
- Inspiratory time-to–expiratory time (I/E) ratio: 1:2 (inspiratory time of 0.4 to 0.7 second)

For children weighing more than 10 kg, a volume-limited system should be used. The following are recommended initial ventilator settings:

- Volume: 10 to 15 mL/kg (if plateau pressure is greater than 35 mm H₂O and for asthmatics, decrease to 6 to 8 mL/kg)
- Rate: an for infant, 20 to 30 breaths/min; for a child, 15 to 20 breaths/min
- FI₀₂: 100% (wean slowly based on pulse oximetry)
- PEEP: 3 to 5 cm H₂O
- I/E ratio: 1:2

**THE DIFFICULT PEDIATRIC AIRWAY**

**Failed Intubation**

In the event that endotracheal intubation is unsuccessful, several options are available for airway rescue. The laryngeal mask airway (LMA) has the advantages of easy placement without the need for laryngoscopy and little cardiac effect during the insertion process. Disadvantages include the lack of airway protection from vomiting or aspiration of gastric contents, the requirement that the patient be unconscious or sedated for placement, and the fact that an LMA is not a definitive airway. Furthermore, in children less than 30 kg, higher ventilatory pressure may be required because the LMA can fold the epiglottis over and cause partial upper airway obstruction.

Approximate LMA sizes are listed in Table 13.6.

Complications of LMA placement are partial upper airway obstruction, coughing or bronchospasm, aspiration or

**Needle Cricothyrotomy (Jet Ventilation)**

Needle cricothyrotomy should be used when endotracheal intubation is not successful. It is most often indicated in children younger than 10 to 12 years, in whom a surgical airway is technically difficult to perform. This chapter describes various oxygen setups that can be used in any emergency department to ventilate by needle cricothyrotomy without a jet ventilator attachment. The procedure for placing the needle is quite simple:

1. Identify the cricothyroid membrane; prepare with povidone-iodine solution if possible.
2. Use a 12- to 14-gauge angiocatheter attached to a syringe to puncture the cricothyroid membrane.
3. Direct the catheter at a 45-degree angle caudally (toward the patient’s feet). Placement of normal saline in the syringe helps demonstrate when air is aspirated.
4. Remove the needle from the angiocatheter.

With these methods the child can be oxygenated, but ventilation (CO₃ exhalation) is limited.

**Methods of Ventilation**

Once the angiocatheter is placed, one of the following methods may be chosen for ventilation:

- Attach the following items to the angiocatheter: a 3-mL syringe barrel, a 7.0 French (F) endotracheal tube adapter, and a bag-valve-mask ventilator. Turn the wall oxygen (O₂) up to 15 L and attempt to administer ventilation with the bag through the angiocatheter.
- Attach a 3.0 F endotracheal tube adapter directly to the angiocatheter and then a bag-valve-mask ventilator; turn the wall O₂ up to 15 L and attempt to administer ventilation with the bag and through the angiocatheter.
- Attach one prong of a nasal cannula to the angiocatheter and use the other prong for oxygen flow (1 second on for inspiration, 4 seconds off for expiration).
- Use an Enk Oxygen Flow Modulator Kit (Cook Medical).
- The QuickTrach kit (Rusch, Inc.) can also be used for cricothyrotomy.

Compensated shock is defined by the presence of tachycardia, cool extremities, prolonged capillary refill time, and weak peripheral pulses with normal systolic blood pressure. Decompensated shock occurs when hypotension, weak central pulses, and weak or absent peripheral pulses develop. Table 13.7 lists the most commonly used medications for maintaining cardiac output and for postresuscitation stabilization.

**PERIPHERAL INTRAVENOUS LINES**

The large peripheral veins, including the antecubital and saphenous veins, are good options in patients of all ages; a small, 20- to 24-gauge catheter may be necessary. Scalp veins and the external jugular veins are also excellent options if intravenous access in the extremities is difficult.

**INTRAOSSEOUS ACCESS**

An intraosseous line should be considered when emergency access is necessary and peripheral vascular access cannot be obtained. The preferred site for placement of an intraosseous line is the anteromedial surface of the proximal end of the tibia 1 cm inferior and 1 cm medial to the tibial tubercle. Alternative sites are the distal end of the femur, the medial malleolus, the distal end of the humerus, and the anterior superior iliac crest. In older children and adults, attempts at intraosseous access may be made in the distal ends of the tibia and the radius and the ulna. In addition to commercially available intraosseous infusion needles (EZ-IO, BIG [Bone Injection Gun]), 15- and 18-gauge Jamshidi-type bone marrow aspiration needles are often used. Contraindications to placement of an intraosseous vascular line are a current attempt in the same area, cellulitis, fracture in the same bone, and osteogenesis imperfecta (relative contraindication).

The procedure for establishing intraosseous access in the anterior part of the tibia is as follows:

1. The skin over the anterior surface of the tibia is sterilized.
2. Starting 1 to 3 cm below the tibial tuberosity (to avoid damaging the growth plate), the needle is directed at a 90-degree angle to the medial surface of the tibia.

IV/IO, Intravenously; IV, intravenously.
3. Once the cortex is passed, the operator must stop pushing to avoid forcing the needle through the other side of the bone.

The following signs help confirm that the needle is in the marrow cavity:

- A sudden decrease in resistance is felt as the needle passes through the cortex.
- The needle stands upright without support.
- When a syringe is attached to the needle, bone marrow may be aspirated. If this is not possible, an infusion flush should be used because it is common to be unable to aspirate marrow.
- Fluid infuses freely without signs of subcutaneous infiltration.

Any drug or fluid that can be administered intravenously can be infused rapidly through an intravenous line. It should be noted that intravenous lines are high-pressure systems; any fluid must be infused via either a pump or syringe. The aspirate can be sent for all laboratory studies except a complete blood count. Complications of intravenous infusions are rare but include growth plate damage, osteomyelitis, compartment syndrome, tibial fracture, and skin necrosis.

CENTRAL VENOUS ACCESS

Emergency indications for central venous access are an inability to establish peripheral venous or intraosseous access and monitoring of a hemodynamically unstable patient.

A 3 or 4 F percutaneous central venous catheter should be used in infants younger than 1 year and a 4 to 5.5 F catheter in children 1 year to 12 years of age. The subclavian, internal jugular, or femoral vein may be accessed with the percutaneous central venous catheter. The femoral vein is the easiest and safest central vein to cannulate in emergencies because of its large diameter and ability to be cannulated while CPR is in progress. The procedure is as follows:

1. The leg is slightly externally rotated and the area prepared and draped in sterile fashion.
2. The femoral vein is located medial to the femoral artery.
   In conscious patients, the area below the inguinal ligament, medial to the femoral artery, should be infiltrated with 1% lidocaine.
3. In children, the introducer needle is directed at a 30- to 40-degree angle to the skin, starting about 1 cm below the inguinal ligament and aiming toward the contralateral shoulder or umbilicus.
4. Once a flash of blood is obtained, the guidewire is threaded through the introducer.
5. The Seldinger technique is then followed to complete line placement.

RESUSCITATIVE DRUGS

EPINEPHRINE

The initial intravenous or intraosseous dose of epinephrine for patients in pulseless arrest who are older than neonates is 0.01 mg/kg (0.1 mL/kg) of a 1:10,000 standard epinephrine solution. All endotracheal doses are 0.1 mg (0.1 mL/kg) of a 1:1000 solution for pulseless arrest. Note that intravenous epinephrine and endotracheal epinephrine doses have the same number of milliliters; only the concentration of the drug changes. Little evidence exists that endotracheal administration improves outcomes. Though reasonable to perform when alternative access is not available, endotracheal administration should not delay establishing intravenous or intraosseous access. These doses may be administered every 3 to 5 minutes during arrest. Evidence suggests that high-dose epinephrine may worsen outcomes; consequently, PALS guidelines no longer recommend high-dose epinephrine except for special circumstances such as beta-blocker overdose. For bradycardia, epinephrine may be given intravenously or intraosseously at 0.01 mg/kg (0.1 mL/kg) of a 1:10,000 solution or 0.1 mg/kg (0.1 mL/kg) of a 1:1000 solution via endotracheal tube.

VASOPRESSIN

Although some adult studies have investigated the use of vasopressin for cardiac arrest, the pediatric literature to date does not provide clear evidence for its use in children. One pediatric study revealed that the use of vasopressin was associated with lower return of spontaneous circulation and a trend toward lower 24-hour and discharge survival.

ATROPINE

Atropine increases the heart rate and may help improve cardiac output. Atropine is indicated for symptomatic bradycardia associated with increased vagal tone or primary atrioventricular block after oxygenation-ventilation and epinephrine have been administered. It is also helpful in decreasing the vagolytic effects of airway manipulation in infants and children during intubation.

The recommended dose of atropine is 0.02 mg/kg, with a minimum dose of 0.1 mg (maximum single dose, 0.5 mg in children and 1.0 mg in adolescents); use of less than 0.1 mg may result in paradoxic bradycardia. The total of the two maximum doses should not exceed 1.0 mg in children or 2.0 mg in adolescents. The most efficacious dose of endotracheal atropine is unknown, but the currently recommended dose is 0.03 mg/kg.

ELECTROLYTES

In infants and small children, the small reserve of endogenous glucose in the form of hepatic glycogen is readily exhausted during stress. In resuscitation settings, access to rapid and accurate bedside glucose testing is essential. Serum levels of glucose and lactate, its anaerobic end product, can be monitored during the resuscitation process. If needed, glucose can be given intravenously or intraosseously at a dose of 2 to 4 mL of 25% dextrose in water (D$_{5w}$) per kilogram. Peripheral vein sclerosis can occur in neonates if high glucose concentrations are used; therefore, D$_{10w}$ should be used in neonates (range, 2 to 10 mL).

Per the 2010 PALS update, routine administration of calcium is not recommended and has been shown to be associated with worse outcomes in pediatric CPR. Indications for administration of calcium are calcium channel blocker toxicity, hypocalcemia, hyperkalemia, and hypermagnesemia. Calcium chloride (10%) in a dose of 20 mg/kg (0.2 mL/kg) is the calcium solution of choice but can be administered only...
via an intravenous or central line. Magnesium at a dose of 25 to 50 mg/kg (maximum, 2 g) may be used for hypomagnesemia or torsades de pointes.

According to the latest PALS consensus guidelines, routine administration of sodium bicarbonate is not recommended for pediatric arrest because it has been associated with decreased survival, but it may be indicated for cases of hyperkalemia or toxic ingestion (e.g., tricyclic antidepressants or other drugs with sodium channel–blocking effects). For specific indications, sodium bicarbonate can be given intravenously or intraosseously at a dose of 1 mEq/kg.

ADENOSINE

Adenosine is a short-acting agent that slows conduction through the atrioventricular node and also acts to block reentry circuits. The treatment of choice for patients with stable supraventricular reentrant tachycardia, adenosine can be administered to unstable patients while preparing for cardioversion. The starting dose of adenosine is 0.1 mg/kg (maximum initial dose, 6 mg) given as centrally as possible and followed immediately by a 5-mL normal saline flush. The second dose is 0.2 mg/kg (maximum dose, 12 mg). Side effects include facial flushing, chest pain, bronchosospasm, and anxiety. Because of the short half-life of adenosine, these effects resolve within 10 to 20 seconds.

LIDOCAINE

Lidocaine is a class I antiarrhythmic agent that may be used in patients with VT and VF or symptomatic ventricular arrhythmias. The initial dose is a 1-mg/kg bolus (maximum dose, 100 mg), followed by a drip at 20 to 50 mcg/kg/min. The endotracheal tube dose is 2 to 3 mg/kg.

AMIODARONE

Amiodarone is a class III antiarrhythmic agent that is now recommended for patients with VF and pulseless VT and should be administered as a 5-mg/kg bolus. The dose may be repeated up to a maximum of 15 mg/kg. Amiodarone can also be used for VT with a pulse or for supraventricular tachycardia (SVT) at a dose of 5 mg/kg infused over a 20- to 60-minute period. It is important to avoid concomitant use of amiodarone and procainamide because this combination can precipitate hypotension and QT prolongation.

PROCAINAMIDE

Procainamide may also be used for VT with a pulse and for SVT. The dose is 15 mg/kg given over a period of 30 to 60 minutes. Amiodarone and procainamide should not be routinely administered together because the combination can precipitate hypotension and QT prolongation.

INTERVENTIONS

Defibrillation is the immediate treatment for patients with witnessed pulseless VT or VF. If the time of arrest is unknown, CPR should be initiated for 2 minutes (five cycles) before attempts at defibrillation. “Stacked shocks” are no longer recommended. Instead, each shock should be followed by 2 minutes of CPR.

Synchronized cardioversion energy levels for SVT and unstable tachyarrhythmias are 0.5 to 1.0 J/kg, whereas unsynchronized cardioversion (defibrillation) for VF or pulseless VT starts at 2 J/kg. Figure 13.2 illustrates an algorithm for potentially lethal arrhythmias. The new 2010 AHA guidelines recommend that the second and subsequent defibrillation attempts use 4 J/kg. A maximum of 10 J/kg may be attempted if the provider believes it to be warranted.

Management of pulseless electrical activity in children is similar to that in adults. The airway should be controlled, intravenous access obtained, and CPR initiated. Specific, treatable causes of pulseless electrical activity should be sought, including hypovolemia, hypoxemia, acidosis, hypothermia, hyperkalemia, tension pneumothorax, cardiac tamponade, ingestion of toxic substances, pulmonary embolism, and myocardial infarction. Figure 13.3 outlines the cardiac arrest algorithm.

Airway management should be the initial focus in children with bradycardia because bradycardia is often secondary to respiratory compromise. Epinephrine is the initial drug of choice. Unlike adults, atropine is not typically the first-line agent for bradycardia in children. It may be used for bradycardia secondary to increased vagal tone, cholinergic drug toxicity, or atrioventricular block. In these situations, atropine may be used before epinephrine, but if no response is noted, epinephrine should be given. Pacer placement may be warranted if pharmacologic agents are not successful. The Broselow-Luten resuscitation tape relates the patient’s length to weight and the appropriate drug dosages and equipment sizes.

If handheld paddles are being used, it is important not only to use the right size but also to position them correctly. The recommended paddle diameter for small children (less than 10 kg) is 4.5 cm; paddles up to 8 cm in diameter are used in larger children and adolescents. If only large paddles are available, they should be placed in the anteroposterior position. Regardless of position, a proper conducting medium must be used along with full paddle contact on the chest wall. The largest paddles or self-adhering electrodes that fit the child’s chest and allow a 3-cm distance should be used. Electrode gel must be used on manually applied paddles.

Automatic external defibrillators (AEDs) are being used more commonly and may be effective. Some AEDs have pediatric dose attenuators, but if this device is unavailable, a standard AED should be used. According to the 2010 AHA guidelines published in the journal Circulation, in infants younger than 1 year, a manual defibrillator is recommended; if not available, the second choice is an AED with a pediatric dose attenuator. A standard AED may be used if neither a manual defibrillator nor an AED with a dose attenuator is available.

should be performed before the physical examination. The PAT provides a rapid assessment of the child’s oxygenation, ventilation, and perfusion and can help categorize the patient into a triage level. Normal vital signs by age are listed in Table 14.1. The PALS formula for blood pressure is $70 + (2 \times \text{age in years})$. It is important to note that this formula defines the 5th percentile for systolic blood pressure in children. Therefore, the preferred formula is $90 + (2 \times \text{age in years})$ because this is the 50th percentile for blood pressure. In the newborn period, normal systolic blood pressure is 60 mm Hg.

The following suggestions constitute a general approach to a child in the ED:

• Allow the parent or caregiver to stay with the child whenever possible.
• Ask what name to use for the child, and then address the child by name.
• Use nonmedical terminology when talking with the family, especially when discussing planned interventions, findings, and treatments. Use language that children will comprehend.
• Always provide privacy no matter how young the child.
• Observe the patient’s level of consciousness, activity level, interaction with the environment and caregiver, position of comfort, skin color, respiratory rate and effort, and level of discomfort before touching the child. Compare the findings on evaluation with the parents’ or caregivers’ description of the child’s normal behavior, such as eating and sleeping habits, activity level, and level of consciousness.
• Be honest with the child and parent or caregiver. Parents or caregivers require reassurance about and explanations of the situation and the anticipated plan of treatment.
• Acknowledge and compliment good behavior, and encourage and praise the child. Provide rewards such as stickers or books.
• Allow the child to make simple age-appropriate choices and to participate in the treatment plan. For example, ask the child which arm to use for measuring blood pressure.
• Encourage play during the examination and any procedures. Use diversion and distraction techniques, such as encouraging the child to blow bubbles and blow the hurt away. Ask the child to sing a favorite song, and sing along or have the parents or caregivers do so. Have the child picture a favorite place and describe it in detail with all five senses.
• Give the child permission to voice any feelings. Tell the child that it is okay to cry. Sympathy is essential.

Each stage of childhood development brings particular anatomic, physiologic, and developmental features that affect assessment and management.

The emergency department must have the resources immediately available for stabilization of critically ill children. Written transfer agreements for specialized care are imperative.

Parents or caregivers must be considered during every interaction with a child, especially if the child is seriously injured or ill. A child’s anxiety and fear often reflect what the child feels or sees in the caregivers.

Family presence during invasive procedures and resuscitation can be a positive experience for some caregivers, especially those treating children with chronic illnesses.

**KEY POINTS**

- Each stage of childhood development brings particular anatomic, physiologic, and developmental features that affect assessment and management.
- The emergency department must have the resources immediately available for stabilization of critically ill children. Written transfer agreements for specialized care are imperative.
- Parents or caregivers must be considered during every interaction with a child, especially if the child is seriously injured or ill. A child’s anxiety and fear often reflect what the child feels or sees in the caregivers.
- Family presence during invasive procedures and resuscitation can be a positive experience for some caregivers, especially those treating children with chronic illnesses.

**GENERAL APPROACH**

Children account for about 30% of all emergency department (ED) visits; of these, 80% are initially evaluated in a general rather than a pediatric ED. Therefore, it is imperative that the general ED environment be not only child friendly but also child safe.

Children are triaged according to the same general guidelines as adults:

Level 1: Critically ill and need immediate attention
Level II: Emergency
Level III: Urgent
Level IV: Less urgent
Level V: Nonurgent

The pediatric assessment triangle (PAT), which consists of a 15- to 20-second evaluation of the patient’s appearance, mental status, work of breathing, and circulation of the skin, provides a rapid assessment of the child’s oxygenation, ventilation, and perfusion and can help categorize the patient into a triage level. Normal vital signs by age are listed in Table 14.1. The PALS formula for blood pressure is $70 + (2 \times \text{age in years})$. It is important to note that this formula defines the 5th percentile for systolic blood pressure in children. Therefore, the preferred formula is $90 + (2 \times \text{age in years})$ because this is the 50th percentile for blood pressure. In the newborn period, normal systolic blood pressure is 60 mm Hg.

The following suggestions constitute a general approach to a child in the ED:

• Allow the parent or caregiver to stay with the child whenever possible.
• Ask what name to use for the child, and then address the child by name.
• Use nonmedical terminology when talking with the family, especially when discussing planned interventions, findings, and treatments. Use language that children will comprehend.
• Always provide privacy no matter how young the child.
• Observe the patient’s level of consciousness, activity level, interaction with the environment and caregiver, position of comfort, skin color, respiratory rate and effort, and level of discomfort before touching the child. Compare the findings on evaluation with the parents’ or caregivers’ description of the child’s normal behavior, such as eating and sleeping habits, activity level, and level of consciousness.
• Be honest with the child and parent or caregiver. Parents or caregivers require reassurance about and explanations of the situation and the anticipated plan of treatment.
• Acknowledge and compliment good behavior, and encourage and praise the child. Provide rewards such as stickers or books.
• Allow the child to make simple age-appropriate choices and to participate in the treatment plan. For example, ask the child which arm to use for measuring blood pressure.
• Encourage play during the examination and any procedures. Use diversion and distraction techniques, such as encouraging the child to blow bubbles and blow the hurt away. Ask the child to sing a favorite song, and sing along or have the parents or caregivers do so. Have the child picture a favorite place and describe it in detail with all five senses.
• Give the child permission to voice any feelings. Tell the child that it is okay to cry. Sympathy is essential.
• Assess for pain with age-appropriate assessment tools. Elicit from the parents or caregivers the child’s typical response to pain.
• Be cautious about what you say in the presence of an awake or presumed unconscious child.

## GROWTH AND DEVELOPMENT

Although growth and development occur simultaneously, they are discrete and separate processes. Growth refers to an increase in the number of cells and leads to an increase in physical size. Development is the gradual and successive increase in the number of cells and leads to an increase in physical size.

Development is predominantly age-specific and reflects neurologic, emotional, and social maturation. Although there is cross-cultural similarity in the sequence and timing of developmental milestones, cultures exert an all-pervasive influence on developing children.

### Table 14.2 Developmental Milestones

<table>
<thead>
<tr>
<th>AGE</th>
<th>MILESTONES</th>
</tr>
</thead>
</table>
| Newborn | Prone: Lies in flexed attitude, turns head from side to side, head lags on ventral suspension  
Supine: Generally lies flexed with mildly increased muscle tone  
Visual: Fixates to bright lights and close objects in line of vision, “doll’s-eye” movement of eyes on turning of body  
Reflexes: Moro, stepping and placing, grasping, rooting, startle, and Babinski  
Social: Visual preference for human faces |
| 1 month | Prone: Legs are more extended; child holds chin up, turns head; head is lifted momentarily to plane of body on ventral suspension  
Supine: Tonic neck posture predominates; is supple and relaxed, head lags on lifting to sitting position, has tight grasp  
Visual: Follows moving object or person, watches a person  
Social: Body movements in cadence with voice, smiles responsively, becomes alert in response to voice |
| 4 months | Prone: Lifts head and chest in vertical axis with legs extended, rolls front to back  
Supine: Symmetric posture predominates, hands in midline, reaches and grasps objects and brings them to mouth  
Sitting: No head lag on pulling to sitting position, head steady, enjoys sitting with full truncal support, tracks objects through 180-degree horizontal arc  
Standing: When held erect, pushes with feet  
Adaptive: When held erect, pushes with feet  
Reflexes: Lacks Moro reflex  
Language: Coos, says “aah”  
Social: Laughs out loud, may show displeasure if social contact is broken, is excited at sight of food, waves at toys |

### THE FAMILY

The parents and other significant caregivers play a fundamental role in the child’s health care experience. Communicating effectively with the parents or caregivers is critical in obtaining an accurate history and consent for treatment. When the child suffers from pain because of illness or injury, the parents or caregivers experience almost equal anxiety and emotional stress. The parent’s or caregiver’s reaction to the child’s condition will directly affect not only how the child behaves but also the manner in which the medical team approaches the patient.

Innate parental or caregiver instincts may evoke powerful emotional reactions. Such reactions are affected by guilt, fear, anxiety, disbelief, shock, anger, and loss of control. Abandoning a child to a stranger’s care, not understanding what will occur next, and worrying about a child’s condition leave caregivers feeling defenseless. Fear of the unknown, fear of separation, fear of the possibility of significant morbidity or death, and fear of a strange environment may add stress to the parents’ or caregivers’ attitudes about the illness or injury in their child. Parents’ or caregivers’ own anxiety and response to the event may negatively influence the ability to console the child, to understand information communicated by health care providers, to participate in decision making for the child’s care, and to recall discharge instructions.

Parents or caregivers in emotional shock from a child’s acute illness or injury react differently. They may be very quiet, uncommunicative, withdrawn, and unaware of the presence of others. They may appear to ignore and may not answer questions. Alternatively, some parents or caregivers become very demanding, offensive, or rude. Such people, like parents or caregivers who react in other ways, need confident, competent care providers who are able to enlist them in the medical process.
FAMILY PRESENCE
Evidence now suggests that presence of the child’s family during invasive procedures and resuscitation can be positive, especially in children with chronic illnesses. Although many family members and health care providers support the concept of family presence, parents or caregivers are not frequently given the option to remain with the child during invasive procedures. Many providers are concerned that family presence will impede care of the child, that it will be distracting to members of the team providing care, and that it will increase stress in the team. Contrary to this belief, studies have shown that family members do not interfere with health care providers and that the family benefits in a variety of ways from the experience. There is also evidence that children feel less stress when parents or caregivers are allowed to remain during procedures. In addition, when institutions

</tr>
</thead>
</table>
| 6 months | **Prone:** Rolls over, may pivot  
**Supine:** Lifts head, rolls over, makes squirming motions  
**Sitting:** Sits unsupported but falls on hands, back is rounded  
**Standing:** May support most of weight, bounces actively  
**Adaptive:** Resists pull of a toy, reaches out for and grabs large objects, transfers object from hand to hand, grasps with radial palm, rakes at a pellet  
**Motor:** Helps hold bottle during feeding  
**Language:** Babbles, giggles, or laughs when tickled  
**Social:** Responds more to emotions, enjoys looking at a mirror, responds to changes in emotional content, turns to a voice, clicks tongue to gain notice |
| 9 months | **Sitting:** Sits up alone with no support  
**Standing:** Pulls to standing position  
**Adaptive:** Grasps objects with thumb and forefinger, pokes at things with forefinger, picks up a pellet with assisted pincer movement, uncovers a hidden toy, attempts to retrieve a dropped object, releases object to other person  
**Motor:** Crawls or creeps, walks holding onto furniture  
**Language:** Makes repetitive sounds such as “mama” and “dada”; imitates speech  
**Social:** Plays pat-a-cake or peek-a-boo, waves bye-bye, tries to find hidden objects, responds to name, begins to respond to “no” and to one-step commands |
| 1 year  | **Motor:** Walks with one hand held, walks holding onto furniture, takes several steps; drinks from cup with help  
**Adaptive:** Picks up a pellet with unassisted pincer movement of forefinger and thumb, releases a held object to other person on request or gesture, points to desired objects, tries to build tower of 2 cubes  
**Language:** Has 3 simple words, understands approximately 10 words  
**Social:** Plays simple games, makes postural adjustment to dressing, follows simple commands |
| 2 years | **Motor:** Walks up and down stairs with one hand held, jumps and runs well, stands on either foot alone for 1 second, climbs on furniture, kicks and throws ball  
**Adaptive:** Handles spoon well, is able to turn doorknob, makes circular scribbling, imitates horizontal stroke, folds paper once imitatively, can build tower of 6 to 7 cubes, points to named objects or pictures  
**Language:** Puts 3 words together, uses pronouns  
**Social:** Listens to stories with pictures, turns pages of book, observes pictures, helps undress self, often tells immediate experiences, verbalizes toilet needs |
| 3 years | **Motor:** Goes up stairs while alternating feet, rides tricycle, stands momentarily on one foot  
**Adaptive:** Can construct block tower of more than 9 cubes, makes vertical and horizontal strokes on paper but does not join them to make a cross, copies a circle, holds crayon with fingers  
**Language:** Composes sentences of 3 to 4 words, has vocabulary of 900 words  
**Social:** Knows own age and sex, counts 3 objects, knows first and last names, plays simple games, helps in dressing self, washes hands |
| 4 years | **Motor:** Hops on one foot, throws ball overhead, uses scissors to cut out pictures, climbs well, runs and turns without losing balance, stands on one leg for at least 10 seconds, catches bounced ball  
**Adaptive:** Copies cross and square, draws people with 2 to 4 parts besides head, knows days of week  
**Language:** Counts 4 pennies, tells a story, learns and sings simple songs, has vocabulary of more than 1500 words, easily composes sentences of 4 to 5 words, can use past tense, knows days of week, can ask up to 500 questions a day  
**Social:** Plays with several children with beginning of social interaction and role-playing, goes to toilet alone |
| 5 years | **Motor:** Skips smoothly, can catch ball  
**Adaptive:** Draws triangle from copy, names heavier of 2 weights, knows right and left hand, draws person with at least 8 details  
**Language:** Names 4 colors, repeats sentences of 10 syllables, has vocabulary of more than 2100 words, counts 10 pennies, prints first name, tells age  
**Social:** Dresses and undresses, asks questions about meanings of words, engages in domestic role-playing |
have incorporated family presence into their practice, staff members have remained supportive. Family members who were present for procedures reported that they would do so again and that their grieving behavior was positively affected by the experience.

Before a family member is offered the choice to be present during an invasive procedure, a health care provider must assess whether the person can cope with what will be experienced during the events. A family member who appears out of control or too emotional may be distracting and disruptive to the health care providers during the procedure. In this case, it may not be advisable to offer the opportunity for family presence. A designated member of the staff who functions to support the family and serve as a patient and caregiver advocate should stay with the family regardless of whether family members decide or are allowed to be present with the child.

The choice to remain present during invasive or resuscitation procedures must be made by the parent or caregiver. If the parent or caregiver prefers to not stay with the child, ED personnel must respect that decision and continue to provide appropriate support and explanations. If the parent or caregiver chooses to stay with the child, the health care team must ensure that this person is given a clear explanation of the procedure and expected responses.

Before escorting family members into the room of a child who is undergoing a procedure or resuscitation, the health care provider supporting them must prepare them for what they will see. Family members should be instructed about where they should stand while in the room, and if possible, they should have the opportunity to touch the child. The health care provider supporting the family should offer an ongoing account of activities in a gentle, calm, and directive voice.

Should the resuscitation efforts or procedure not result in positive changes in the child’s condition, the health care provider supporting the family must remember that his or her role is to support the family’s presence and to avoid any derogatory comments.

CONFIDENTIALITY AND CONSENT

Implied consent occurs when immediate therapy is required for a child who is critically ill. Direct consent is required when the necessary treatment is not an emergency. In a minor, such consent should be obtained from the parent or legal guardian. An emancipated minor is defined as one who lives apart from parents, is pregnant or a married or unmarried mother, is in college, is in the armed forces, or is self-supporting and managing his or her own financial matters. A mature minor is a patient who is a minor but has the intellect and maturity to make an informed, independent decision while understanding the risks and benefits of the recommended therapy. The age of maturity varies between states but in general ranges between 14 and 16 years of age.

Consent related to confidentiality issues is typically under the purview of state law. Treatment of sexually transmitted diseases, pregnancy-related conditions, and substance abuse concerns is an important issue that the emergency physician must be prepared to manage. Breach of confidentiality of these issues should only occur if physical or sexual abuse is a concern or if the child is homicidal or suicidal.

REFERENCES

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

The average neonate eats between six and nine times a day. Intervals between feeding may range from 2 to 4 hours. Breastfed infants tend to eat more often than formula-fed infants.

**Sleeping**

Newborns sleep 16 to 18 hours per day, with almost equal amounts of day and night sleep. Awake periods are generally about 1 to 2 hours in duration.

**Vital Signs**

A normal neonatal pulse is in the range of 120 to 160 beats/min, but it rises if the child is stimulated. The heart rate slows during sleep.

The normal respiratory rate is between 40 and 60 breaths/min. Some irregularity and pauses of less than 20 seconds are normal in the neonatal period. Respiratory pauses should not be associated with any change in color or hypotonia. Because of this irregularity in respiratory rate, accurate measurements can be obtained only if breaths are counted for at least 30 seconds.

Measuring blood pressure in a newborn can be frustrating and time-consuming. A Doppler probe can facilitate the procedure. A systolic blood pressure of less than 60 mm Hg is abnormal in a neonate.

The core temperature in an infant is the same as that in an adult. Fever is generally recognized as a temperature higher than 38°C (100.4°F). Any temperature lower than 36.1°C (97°F) should raise concern for hypothermia. Because of limited thermoregulatory ability, neonates should be examined and treated in a warm ambient environment. See Table 15.1 for normal neonatal vital signs.

**Apnea and Apparent Life-Threatening Events**

**Epidemiology**

General estimates suggest that between 0.5% and 6.0% of infants will experience an apparent life-threatening event (ALTE). A prospective Austrian study conducted from 1993 to 2001 revealed an incidence of 2.46 per 1000 live births. In this study more than 60% of the events occurred in infants 2 months or younger.

**Pathophysiology**

ALTE is not a single disease entity but rather a constellation of signs and symptoms of numerous diseases that can have
lethal consequences. The 1986 National Institutes of Health Consensus Development Conference on Infantile Apnea and Home Monitoring defined ALTE as “an episode that is frightening to the observer and is characterized by some combination of apnea (central or occasionally obstructive), change in color (usually cyanotic or pallid, but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging.”

The conventional definition of apnea is absence of breathing for 20 seconds or for a shorter period if associated with clinical signs such as cyanosis, hypotonia, and bradycardia. Because periods of apnea of up to 30 seconds have been observed in normal, healthy, asymptomatic term and preterm infants, the duration of apnea does not seem to be as clinically important as apnea associated with signs and symptoms. Apnea should be distinguished from the normal
periodic breathing of newborns, which is characterized by irregular breathing and episodes of pauses. This latter pattern is more commonly seen in premature infants during sleep. Although similarities exist, ALTE is now considered a different pathophysiologic entity from sudden infant death syndrome.

**PRESENTING SIGNS AND SYMPTOMS**

The majority of neonates who have experienced an ALTE have a normal appearance at the time of arrival at the ED. Stratton et al. reported a prehospital study of 60 cases of ALTE in which 83% of the infants were asymptomatic by the time that emergency medical service personnel arrived. A comprehensive history and a thorough physical examination should be performed. One study showed that the history and physical examination were helpful in diagnosing the cause of ALTE in 70% of cases. The history should consist of a detailed description of the event, a prenatal and perinatal history, a review of systems, and a family history (especially child deaths, neurologic diseases, cardiac diseases, and congenital problems).

**Box 15.1** lists essential historical questions in these cases. A detailed physical examination should pay particular attention to the neurologic, respiratory, cardiac, and developmental components. Evidence of child abuse should be sought, including a funduscopic examination for retinal hemorrhage.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

ALTEs and apnea are clinical manifestations that have many causes, as summarized in **Box 15.2**. The most common organ systems involved (in order of decreasing frequency)

are the gastrointestinal, neurologic, respiratory, cardiac, metabolic, and endocrine systems. The cause of ALTE in an individual patient is likely to be discovered only about 50% of the time.

Diagnostic testing is best guided by the history and physical examination. Laboratory tests have been shown to be contributory to the diagnosis only 3.3% of the time if the results of the history and physical examination were noncontributory.6 An Israeli study concluded that diagnostic testing has low yield in infants with normal perinatal histories and normal findings on physical examination.7

### DISPOSITION

Historically it has been the practice that all infants with apnea or ALTE be admitted for observation. Some studies suggest that certain low-risk infant groups might be able to be discharged home from the ED.6,8 Box 15.3 lists low-risk criteria for ALTE. An infant meeting all the criteria in this box would have a very low probability of experiencing an adverse outcome. Otherwise, it is prudent to admit the infant for observation and in-patient evaluation by a pediatric specialist.

### EXCESSIVE CRYING AND IRritability

Crying peaks in infancy at 6 weeks of age with an average crying time of 3 hours per day. More of the crying time is clustered in the late afternoon and evening. Forty percent of these infants cry for 30 minutes or longer at one time, 75% of whom have the longest crying spells between 6 and 12 pm.10 The prevalence of excessive crying varies between 1.5% and 11.9%, depending on the definition of excessive crying.11

### PATHOPHYSIOLOGY

Crying is a form of communication by the neonate. It signals some form of infant discomfort from hunger to lack of attention to other causes of pain, some that can be serious.

### PRESENTING SIGNS AND SYMPTOMS

Box 15.4 lists important questions to ask the caregiver of an afebrile infant with excessive crying. Table 15.2 lists possible physical findings in these infants.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The first differentiation that the clinician must make is whether the child is febrile (see the section “Fever”). In an afebrile infant the chronicity of the crying is important. Is the crying an acute single episode, or has it been an ongoing problem for some time?

The latter describes colic, which affects a large subgroup of excessively crying infants. Classically, colic has been described by the rule of threes—crying for 3 hours per day, for at least 3 days per week, for 3 weeks. Scores of theories concerning the etiology of colic have been proposed; such theories range from physiologic disturbances (cow’s milk allergies, gastrointestinal reflux, hypocontractile gallbladder, and other gastrointestinal disturbances), to infant temperament and maternal response, to deficiencies in parenting practices.12 No single cause has been identified.

No pharmacologic agent has been listed as being both safe and efficacious for the treatment of colic. Anticholinergic agents have been found to be more effective than placebo but are associated with apnea and should not be administered to infants younger than 6 months.13 Many other interventions have been proposed for colic, such as having the infant in a car, specific ways to hold the infant, use of white noise, crib vibrators, and herbal teas. None have been shown to be particularly beneficial, however. The EP should reassure parents that there is no ideal treatment of colic, that their child is normal, that the infant will outgrow the colic, and that colic has no long-term sequelae.

A retrospective study involving 237 afebrile children younger than 1 year brought to the ED with the chief complaint of crying or fussiness revealed that 5.1% had a serious underlying etiology. The final diagnosis in the 237 patients was made by the history and physical examination alone in
Treatment is determined by the underlying condition causing the crying.

DISPOSITION

Afebrile crying infants may be discharged home if they are consolable, if they have a negative history and physical examination, and if the clinician has a low index of suspicion for a “sick” child.

CYANOSIS

Cyanosis is the result of either deoxygenated hemoglobin or abnormal hemoglobin (methemoglobin). Cyanosis occurs with the presence of 4 to 5 g of deoxygenated (unsaturated or reduced) hemoglobin per 100 mL of blood. This is an absolute quantity and not a percentage of unsaturated hemoglobin. A cyanotic, polycythemic infant with a hemoglobin value of 18 g/100 mL might have no tissue hypoxia if the total amount of unsaturated hemoglobin is only 5 g/100 mL because the oxygen content of the blood would still be adequate. Conversely, an anemic infant with a hemoglobin value of 7 g/100 mL would have severe tissue hypoxia because at least 4 to 5 g/100 mL of the total is deoxygenated hemoglobin.
Cyanosis in a neonate may be persistent or transient, central or peripheral (acrocyanosis). The EP can best evaluate cyanosis clinically by looking at the tongue and mucous membranes. Duskyness or blueness in these areas defines central cyanosis, a pathologic condition. In peripheral cyanosis, or acrocyanosis, the extremities are blue but the oral mucosa and tongue remain pink; this pattern is frequently a normal finding in a neonate but can be associated with pathologic oxygenation.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

An easy method of classifying cyanosis is by causative organ system (Box 15.5). The cardiac and respiratory systems are responsible for the large majority of cases of neonatal cyanosis. Distinguishing between these two categories can be difficult but is necessary for optimal management of the patient.

An echocardiogram is the most definitive test that can be performed in the ED to distinguish between pulmonary and cardiac causes of cyanosis. If unavailable, the next best test would be the hyperoxia-hyperventilation test (also called the 100% oxygen challenge test), and it is performed as follows:

1. Blood gas analysis is performed with the infant breathing room air.
2. The patient is then administered 100% oxygen, and the blood gas values are determined again.

If the hypoxia is secondary to pulmonary disease, PaO₂ usually rises to greater than 150 mm Hg with 100% oxygen. If the hypoxia is secondary to right-to-left cardiac shunting from congenital heart disease, the PaO₂ value does not rise significantly when the infant is receiving 100% oxygen. Occasionally, enough intrapulmonary right-to-left shunting occurs in lung disease to prevent a rise in PaO₂ with the simple administration of 100% oxygen. In these cases the infant can be manually ventilated with 100% oxygen, and PaO₂ rises if the source of cyanosis is in the lungs. In many instances these results are obtained clinically by the infant’s response to oxygen during the initial resuscitation.

Though rare, methemoglobinemia is a possibility in a cyanotic neonate. This syndrome may be inherited or acquired. The acquired form is typically due to drugs and toxins such as nitrites, anesthetics, and aniline dyes, but it may occur as a result of diarrhea and acidosis.

**TREATMENT**

The initial treatment of any neonate with cyanosis includes adequate supplemental oxygenation, ventilation, and an intravascular volume challenge with 10 to 20 mL/kg of normal saline (NS). If no response is seen to volume resuscitation, vasopressor support with dopamine, 5 to 20 mcg/kg/min, should be instituted.

If a cyanotic neonate continues to show signs of inadequate tissue oxygenation after the initial resuscitation, prostaglandin E₁ (alprostadil) should be given intravenously (IV) starting at 0.05 to 0.1 mcg/kg/min. Administration of prostaglandin is frequently associated with apnea, fever, and occasionally shock. The EP should be prepared to intubate the infant if such complications arise. One study has shown that aminophylline given as a 6-mg/kg bolus before the administration of prostaglandin E₁, followed by 2 mg/kg IV every 8 hours for 72 hours, significantly reduces apnea.

Acquired methemoglobinemia is treated with methylene blue, 1 to 2 mg/kg IV as a 1% solution delivered over a 5-minute period.

**DISPOSITION**

An acutely cyanotic infant will require admission to the hospital for evaluation and treatment. An infant with known
cyanotic heart disease may be able to be discharged, but discharge should be done only in consultation with the infant’s cardiology specialist.

**DIFFICULTY BREATHING**

**PATHOPHYSIOLOGY**

Difficulty breathing may arise from pathology in the heart, lungs, or central and peripheral nervous systems. Toxins and systemic illness, such as sepsis and acidosis, can cause breathing difficulty. Regardless of cause, immediate evaluation is required.

**PRESENTING SIGNS AND SYMPTOMS**

Respiratory distress involves a spectrum of clinical findings from apnea, dyspnea, tachypnea, stridor, nasal flaring, grunting, chest retractions, wheezing, and rales to simple nasal congestion and periodic breathing. Tachypnea (fast breathing) should be distinguished from dyspnea (increased work of breathing) because lung pathology is more likely to be associated with dyspnea. Rapid, unlabored respirations are more likely to be seen in neonates with metabolic acidosis and cardiac pathology. Stridor is a symptom of upper airway obstruction from either intrinsic or extrinsic causes.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

A list of potential causes of respiratory distress that can occur anytime during the first 28 days is presented in Box 15.6. The majority of causes are pulmonary, cardiac, or infectious. Diagnostic testing includes a complete blood count, serum glucose measurement, metabolic profile, blood cultures, arterial blood gas measurements, urinalysis, urine culture, chest radiography, and electrocardiography.

The differential diagnosis of pulmonary causes of respiratory distress in a neonate can be divided into syndromes manifested in the first hours of life and those manifested anytime during the first 28 days. The former group includes transient tachypnea of the newborn, respiratory distress syndrome, persistent pulmonary hypertension of the newborn, and meconium aspiration syndrome. These conditions are not discussed further because they are almost certainly diagnosed and treated in the nursery, not the ED.

Pneumonia is the most common and most serious infectious cause of respiratory distress in the first 28 days of life. From a clinical perspective, neonatal pneumonia can be divided into early-onset and late-onset types (Table 15.3).

The clinical findings of neonates with pneumonia can be atypical. Signs of respiratory distress are generally present, but they may be absent. Gastrointestinal symptoms, such as vomiting, abdominal distention, and poor feeding, may predominate. General systemic signs such as lethargy, ill appearance, poor feeding, and jaundice may be the initial complaints. The classic radiographic appearance consists of bilateral alveolar densities with air bronchograms. Hyperinflation of the lungs without evidence of infiltrate is a common early

The initial management of all newborns with difficulty breathing is to follow the ABCs (airway, breathing, circulation) of neonatal resuscitation.

Antibiotic coverage for early-onset pneumonia consists of ampicillin, 150 mg/kg IV every 12 hours if meningitis is suspected. If meningitis is not suspected, 50 to 100 mg/kg IV every 12 hours is adequate. Intravenous gentamicin is given according to gestational age and renal function. For infants born after 35 weeks of gestation, the dose is 4 mg/kg every 24 hours; for those born between 30 and 35 weeks of gestation, the dose is 3 mg/kg every 24 hours. In neonates with late-onset neonatal pneumonia, some authorities would recommend administering vancomycin, 15 mg/kg IV every 12 hours with gentamicin, instead of ampicillin until the results of culture are available. If herpes simplex virus pneumonia is suspected, acyclovir, 20 mg/kg IV every 8 hours (in infants with normal renal function), should be started. All neonates with pneumonia should be admitted to the hospital.

In an infant with cardiovascular collapse from a ductus-dependent left-sided heart obstruction, the only nonoperative way to maintain adequate systemic perfusion is to keep the ductus arteriosus patent. This is done on an emergency basis by the administration of a continuous infusion of prostaglandin E1 (alprostadil). The initial dose is 0.05 to 0.1 mcg/kg/min IV, with a maintenance dose titrated to the lowest dose effective in maintaining patency. Treatment of a stridulous infant initially depends on the degree of respiratory distress. If respiratory distress is present, it is best to not manipulate the child too much unless emergency airway interventions are necessary. If possible, the EP should perform the physical examination of a stridulous infant in distress in the presence of an otolaryngologist or pediatric surgeon who can obtain a surgical airway immediately in a controlled setting (operating suite). A neonate with stridor should be admitted to the hospital unless the EP is certain that the child is stable and the cause of the stridor is not progressing.

FEVER

Fever is defined as a rectal temperature of 38°C (100.4°F) or higher. The majority of febrile illnesses in infants are self-limited viral infections. Ten percent to 20% of febrile infants younger than 3 months have a serious bacterial infection (SBI), defined as bacterial meningitis, bacteremia, urinary tract infection, pneumonia, skin or soft tissue infection, bacterial enteritis, septic arthritis, or osteomyelitis. Bacteremia is twice as likely to occur in the first month of life as in the second month.
PATHOPHYSIOLOGY

A neonate’s immature immune system lacks the ability to localize and contain infection; therefore, the newborn may not show specific signs of serious underlying disease. The birth process exposes the infant to an array of bacterial and viral pathogens. The most common bacterial pathogens in the first 28 days of life are group B streptococci and *Escherichia coli*. Other bacteria may be gram-negative (e.g., *Klebsiella, Enterobacter, Salmonella*) or gram-positive organisms (*Staphylococcus aureus, Enterococcus*, other streptococcal species, and *Listeria monocytogenes*). Herpes simplex virus and the enteroviruses can also cause febrile illness in neonates. Neonatal herpes can be a devastating illness, with only about half the cases caused by active maternal infection.

PRESENTING SIGNS AND SYMPTOMS

A febrile neonate may look remarkably well or may be extremely toxic appearing.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

**Box 15.8** present a work-up for a febrile infant younger than 28 days.

Recent literature suggests that C-reactive protein levels can predict infection. The limitation to its use is that a period of up to 8 to 10 hours is required for synthesis, so it has a variable range of sensitivity (from 14% to 100%) in the first 24 hours. A cutoff of 70 g/L has been proposed, although it is a nonspecific marker for infection. Procalcitonin also deserves mention as a possible marker for SBI. It is the prehormone of calcitonin and increases within 2 hours of an infection. Its sensitivity is 92.6% with a specificity of 97.5% if obtained outside the first 48 hours of life.

TREATMENT

Empiric antibiotic treatment of neonatal sepsis consists of either ampicillin and gentamicin or ampicillin and cefotaxime.

(Boxes 15.9 and 15.10). If neonatal meningitis is suspected, ampicillin and cefotaxime are preferred. Some authorities would add gentamicin as a third antibiotic for suspected meningitis when no organisms are seen on Gram stain of cerebrospinal fluid. Herpes simplex virus infection should be strongly considered in febrile infants with seizures and abnormal cerebrospinal fluid results. Skin lesions and abnormal liver function values should further increase suspicion for this disorder. An infant with suspected herpes simplex virus infection should receive acyclovir, 60 mg/kg/day in three divided doses (20 mg/kg per dose). Acyclovir should be continued until the results of herpes simplex virus polymerase chain reaction are negative. Neonates with an identifiable viral infection (e.g., respiratory syncytial virus) have as high as a 7% chance of having a concomitant SBI. Therefore, a septic evaluation should be performed in any child 1 to 28 days old with fever despite an identifiable viral infection. Antibiotics should be administered empirically to this group. Febrile neonates should be admitted to the hospital.

VOMITING

SCOPE

Vomiting is defined as forceful diaphragmatic and abdominal wall contraction with simultaneous relaxation of the stomach, gastroesophageal sphincter, and esophagus and closure of the gastric pylorus. Regurgitation, or “spitting up,” is a nonforceful reflux of milk or gastric contents into the mouth. Regurgitation is generally a benign disorder but can occasionally be associated with gastroesophageal reflux disease and result in serious consequences such as apnea.
PATHOPHYSIOLOGY

The appearance of the vomitus is important. Bilious vomit suggests obstruction below the ampulla of Vater. Undigested milk may simply be regurgitation but could be caused by gastrointestinal obstruction above the ampulla of Vater. Bloody vomitus requires a search for upper gastrointestinal bleeding.

SIGNS AND SYMPTOMS

It is important to distinguish between bilious vomiting and nonbilious vomiting. If bilious vomiting is reported, it is assumed to be obstructive and a surgical emergency until proved otherwise. Studies have suggested that 20% to 50% of neonates with bilious emesis within the first week of life have a surgical condition.\(^3\)

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Causes of vomiting can be divided into anatomic and nonanatomic categories (Box 15-11).

<table>
<thead>
<tr>
<th>Anatomic Causes</th>
<th>Nonanatomic Causes</th>
</tr>
</thead>
<tbody>

</tr>
</tbody>
</table>

Volvulus from midgut malrotation can be manifested as a sudden onset of bilious vomiting, duodenal obstruction as a result of obstructing Ladd bands, or intermittent vomiting with failure to thrive. Most neonates with volvulus will appear to be well, but if necrosis of the gut or ischemia has begun, they may appear ill or in shock. Abdominal radiographs should be obtained if obstruction is a concern.

To make the diagnosis of volvulus secondary to midgut malrotation promptly, an upper gastrointestinal contrast-enhanced study is needed. The small intestine will have a “corkscrewing” appearance with the intestine rotated to the right side of the abdomen with midgut volvulus.

In dehydrated and toxic infants, a complete blood count, serum glucose and electrolyte measurements, and a septic evaluation should be performed.

A healthy-appearing infant with vomiting but appropriate weight gain and normal vital signs requires no diagnostic testing.

TREATMENT

If the infant is moderately or severely dehydrated, 0.9% sodium chloride should be administered IV as a 20-mL/kg bolus. Oral rehydration may be tried in a mildly dehydrated infant. Nasogastric decompression is required for intestinal obstruction. Empiric therapy with ampicillin and gentamicin or ampicillin and cefotaxime should be administered for suspected sepsis.

In midgut malrotation with volvulus, management includes placement of a nasogastric tube, administration of broad-spectrum antibiotics (gentamicin, clindamycin, and ampicillin), and rapid fluid replacement with NS (20-mL/kg bolus) as needed.\(^3\)

FOLLOW-UP AND DISPOSITION

Infants with regurgitation may be managed as outpatients. Children younger than 28 days with true vomiting should be admitted to the hospital for further evaluation and treatment.

DIARRHEA

SCOPE

Diarrhea is defined as an increase in both the number and the looseness or wateriness of stools. Even in the neonatal period, diarrhea tends to be self-limited without significant morbidity.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Viral infections are common, with rotavirus being the most frequent cause. Other viral causes of diarrhea are enterovirus, enteric adenovirus, and coronavirus. Bacterial diarrhea in neonates is caused by the same organisms found in other
age groups, including *Salmonella*, *Shigella*, *Campylobacter*, *E. coli*, *Vibrio*, *Yersinia*, and *Clostridium difficile*.

*Salmonella* gastroenteritis is potentially dangerous in neonates because of its association with systemic sepsis. Bacteremia may occur in 30% to 50% of neonates infected with this organism. Diarrhea from *Salmonella* gastroenteritis is usually watery with mucus and may appear bloody. This organism is an enteroinvasive bacterium (i.e., it invades the intestinal mucosa), so a methylene blue smear of a stool specimen will reveal white blood cells. Necrotizing enterocolitis (NEC) is one of the more dangerous causes of neonatal diarrhea. It is classically seen in premature infants but can occur in term neonates. Its incidence is also higher in infants with congenital heart disease. The diarrhea is typically bloody and is associated with other symptoms, such as decreased feeding, vomiting, ileus, and abdominal distention. If not treated, symptoms progress to bradycardia, hypothermia, apnea, hypotension, and death. Diagnostic radiographic findings are pneumatosis intestinalis (air in the bowel wall) and air in the portal vein. Intestinal perforation leads to pneumoperitoneum.

**TREATMENT**

Neonates with *Salmonella* gastroenteritis should be treated with cefotaxime, 50 mg/kg IV every 12 hours. Treatment of NEC involves cessation of oral feeding, nasogastric decompression, intravenous fluids, and antibiotics (ampicillin, cefotaxime, clindamycin).

**FOLLOW-UP AND DISPOSITION**

Neonates with suspected bacterial diarrhea or NEC should be admitted to the hospital.

**NEONATAL JAUNDICE**

**EPIDEMIOLOGY**

In almost all newborns, the bilirubin level reaches 2 to 3 mg/dL in the first few days of life. Neonatal jaundice occurs in up to 60% of term infants in the first week of life. Approximately 2% of newborns will reach levels of total serum bilirubin in excess of 20 mg/dL.

**PATHOPHYSIOLOGY**

Hemoglobin degrades to form unconjugated bilirubin. This unconjugated (indirect) bilirubin is lipid soluble and binds to albumin. The bilirubin that is not bound to albumin can cross the blood-brain barrier and injure the brain (kernicterus). Albumin-bound unconjugated bilirubin is transported to the liver and converted to water-soluble conjugated bilirubin (direct bilirubin). Conjugated bilirubin is excreted into bile and then into the gut. Most bilirubin is eliminated from the gut in stool.

**BOX 15.12 Criteria for Physiologic Jaundice**

<table>
<thead>
<tr>
<th>Jaundice occurring after 24 hours of life</th>
</tr>
</thead>
<tbody>
<tr>
<td>Serum bilirubin level rising no faster than 0.5 mg/dL/hr or 5 mg/dL/day</td>
</tr>
<tr>

</tr>
<tr>
<td>No evidence of acute hemolysis</td>
</tr>
<tr>
<td>Jaundice not persisting longer than 10 days in a term neonate or 21 days in a preterm neonate</td>
</tr>
</tbody>
</table>

*Breastfed infants may remain jaundiced up to 2 weeks longer.*

**SIGNS AND SYMPTOMS**

Jaundice is most easily detected in the sclera, skin, and oral cavity.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Jaundice can be normal (physiologic) or abnormal (nonphysiologic). Physiologic jaundice usually becomes visible on the second or third day of life. Jaundice in the first 24 hours of life is always abnormal. Physiologic jaundice is thought to be secondary to the higher breakdown of red blood cells in neonates and transient slowing of conjugation processes in the liver. It peaks at levels between 5 and 12 mg/dL on the third or fourth day of life and then starts to decline. Risk factors for higher levels of physiologic hyperbilirubinemia include a family history of neonatal jaundice, breastfeeding, bruising and cephalohematoma, maternal age older than 25 years, Asian ethnicity, prematurity, weight loss, and delayed bowel movement. Box 15.12 lists the criteria for physiologic jaundice.

Breast milk jaundice develops after the seventh day of life and peaks during the second or third week. It is postulated that a glucuronidase in breast milk causes increased enterohepatic absorption of unconjugated bilirubin. Because of its late onset, breast milk jaundice is almost never a neurologic threat. Laboratory tests are indicated in a jaundiced infant unless the EP is absolutely certain that the jaundice is physiologic. A total serum bilirubin measurement with direct and indirect fractions and a complete blood count are required. A Coombs test for autoimmune hemolysis is indicated if the maternal blood type is O and the fetal blood type is Rh negative and the infant’s blood type is Rh positive or if the maternal blood type is O and the fetal blood type is A, B, or AB. A reticulocyte count is useful for evaluating hemolytic anemia. Because jaundice can be the initial manifestation of hypothyroidism, measurements of serum thyroid-stimulating hormone and thyroxine may be helpful. If the neonate appears ill—has lethargy, decreased feeding, temperature instability, or difficulty breathing—an evaluation for sepsis is indicated.

**TREATMENT**

Early treatment of hyperbilirubinemia ensures adequate hydration and feeding. A breastfed infant should be fed more
often to promote stooling and excretion of bilirubin. Further management of hyperbilirubinemia may involve phototherapy or exchange transfusion. Initiation of these therapies depends on several factors, including the total serum bilirubin level and the infant’s birth weight and age. Some preterm infants are at higher risk for neurologic sequelae, which mandates a lower threshold for initiation of phototherapy.

The American Academy of Pediatrics (AAP) has issued practice guidelines for the treatment of neonatal jaundice. One tool that the EP may find helpful is the website www.bilitool.org, in which parameters may be entered to determine the infant’s risk based on the bilirubin level obtained. The following information is needed to estimate an infant’s risk: (1) the infant’s date of birth and time (to the hour), (2) the infant’s gestational age, and (3) the time that the bilirubin level was obtained. After entering this information, the AAP guidelines will be listed and appropriate therapy recommendations will be displayed based on the level of risk.

**DISPOSITION AND FOLLOW-UP**

Only well-appearing neonates with clearly physiologic or breastmilk jaundice and a serum bilirubin level below the guideline limits for phototherapy should be discharged. Close follow-up and monitoring should be arranged for such infants at the time of discharge. All other infants should be admitted for further testing and treatment.

**METABOLIC EMERGENCIES**

**SCOPE**

Metabolic emergencies account for a small percentage of disorders in neonates seen in the ED. This low incidence accounts for the difficulty recognizing and treating these emergencies. Adrenal insufficiency is one metabolic emergency in neonates that can be encountered in the ED and should be taken into consideration to reduce an infant’s morbidity and mortality.

**PATHOPHYSIOLOGY**

Congenital adrenal hyperplasia (CAH) is the most recognized form of adrenal insufficiency in children and is sometimes identified as part of the initial newborn screening program. It is most commonly associated with the lack of 21-hydroxylase, an enzyme necessary for cholesterol metabolism and required to produce cortisol. This may result in virilization of females and be accompanied by an acute salt-wasting crisis. The male genitalia is not generally affected by CAH, thus making males more susceptible to underdiagnosis.

**PRESENTING SIGNS AND SYMPTOMS**

Dehydration, hypotension, hypoglycemia, and shock are the most common signs seen in the ED. Neonates may also have fatigue, nausea, vomiting, or weight loss. Females may have an enlarged clitoris and fusion of the labial folds, and some females may be mistaken for males. This makes physical examination extremely important for this diagnosis, and close attention should be paid to the infant, with removal of the diaper and inspection of the genital area. The triad of hyponatremia, hyperkalemia, and hypoglycemia should alert the clinician to this possible diagnosis.

**TREATMENT**

The first step is to restore volume with 0.9% NS in 20-mL/kg boluses. Following initial volume replacement, D$_{1,2}$NS is administered at 1 to 1.1 times the maintenance rate. Cortisol replacement should be achieved by administration of hydrocortisone, 1 to 2 mg/kg IV for term infants and then 25 to 100 mg/m$^2$/day divided into three to four doses every 6 to 8 hours. Hyperkalemia is typically well tolerated and saline is usually all that is needed to lower the potassium level. Intravenous calcium gluconate, β-agonists, insulin, and glucose should be available for any potential cardiac arrhythmias.

**CHILD ABUSE**

Child abuse should be included in the topic of neonatal emergencies because it is a potential diagnosis in an infant with apnea, seizures, or altered mental status. If suspicion exists, non–contrast-enhanced computed tomography (CT) of the head should be performed, and if the patient is deemed stable, a skeletal survey should be considered. Any suspicion of child abuse should be reported to the Department of Children and Family Services immediately. The EP should also consider notifying the police because this provides protection for the child and the staff involved in the infant’s care. Studies suggested for the initial work-up of child abuse include a complete blood count, coagulation profile, a chemistry panel, and liver function tests.

REFERENCES

ED are encouraged to develop an expanded differential diagnosis by using their knowledge of anatomy to aid memory (Table 16.2).

**KEY POINTS**

- Use a systematic approach to evaluate and manage infants and toddlers. Know common milestones and age-specific manifestation of illness, take an “AMPLIFIEDD” history, do a “head-to-toe” physical examination, and use the “head-to-toe” memory tool to generate an expanded differential diagnosis.
- Do not make the diagnosis of infantile colic on first episode of excessive crying. Remember Wessel’s rule of 3.
- When the cause of illness in an infant or toddler is not obvious, the emergency practitioner should maintain a high level of suspicion for abuse, accidental toxin ingestion or exposure, intussusception, infection, and nonconvulsive seizure activity.

**DOCUMENTATION**

Infant or Toddler in the Emergency Department

Document consideration of life-threatening diagnoses.

Create a word picture of the child: minor or serious illness; for example:

- “Child is playful, interactive, and taking bottle or fluids well.”
- “Well hydrated, nontoxic, and no evidence of trauma, sepsis, meningitis, or distress.”
- “Alert, good tone, moving all extremities.”
- “Child appropriately cries but can be consoled by caregivers.”

This chapter demonstrates how to take a systematic approach to the evaluation of infants and toddlers in the ED to develop a comprehensive diagnostic and therapeutic plan by using three examples of different clinical manifestations: a crying infant, an infant or toddler with altered level of consciousness, and a vomiting infant or toddler.

**THE CRYING INFANT**

“Birds fly and babies cry”

—Marc Weissbluth, pediatrician

**PERSPECTIVE**

More than 20% of emergency department (ED) visits are by pediatric patients, and a large proportion involve children 4 years or younger. Common reasons for ED visits in this age group include traumatic injuries, fever, respiratory complaints, and gastrointestinal problems. Although many of the disease processes are self-limited, it is imperative that the emergency practitioner (EP) identify infants and children at risk for progression to serious illness.

Knowledge of developmental milestones and age-specific manifestations of illness, in addition to taking a thorough history and physical examination, will greatly enhance the clinician’s ability to diagnose and initiate appropriate therapeutic interventions. From early infancy to the toddler stage, remarkable developmental changes occur. Understanding the changes in language, motor, cognitive, and social skills is important to properly assess infants and toddlers (Fig. 16.1). Many of the common illnesses experienced are age related (Table 16.1), and early recognition of the signs and symptoms of the specific diseases that threaten infants and toddlers is an effective strategy. Taking an “AMPLIFIEDD” history (Box 16.1) and performing a “head-to-toe” physical examination allow the clinician to gather the clinical clues needed to generate a comprehensive differential diagnosis. Practitioners in the ED are encouraged to develop an expanded differential diagnosis by using their knowledge of anatomy to aid memory (Table 16.2).
**Fig. 16.1** Easy-to-remember developmental milestones for the emergency department practitioner.

**Box 16.1 The “AMPLIFIEDD” History**

- **Allergies:** to medications, environmental allergens
- **Medications:** prescription, over the counter, natural remedies
- **Past medical or surgical history:**
  - Birth history
  - Congenital anomaly
  - Chronic disease (e.g., inborn error of metabolism, endocrinopathy)
  - Previous infections
  - Surgeries
- **Last “feed, pee, poop”:** Feeding, stool, and urine pattern; use of formula (dilution?)
- **Immediate events (history of present illness and review of systems):** OLD CAARS
  - Onset: Rapid or gradual
  - Location: Evidence of localized pain?
  - Duration and progression of symptoms
  - Characterization of symptoms
  - Alleviating factors of symptoms
  - Aggravating factors of symptoms
  - Recurrence of symptoms: ever had similar manifestation?
  - Severity and system review
- **Family and social history:**
  - Inherited disorders
  - Day care: Who cares for child?
- **Immunizations up to date?**
- **Emergency medical service history:** Elicit history of potential trauma, ingestion, abuse, or toxin exposure
- **Doctor:** Name of primary care physician or specialist for additional information and help
- **Documents:** Obtain previous medical records

**SECTION II  SPECIAL CONSIDERATIONS IN THE PEDIATRIC PATIENT**

toddler to the ED, they are often exhausted from attempts to console the child. In such circumstances, the EP must be able to distinguish between relatively benign conditions, such as colic, and severe, life-threatening illnesses, such as meningitis. An orderly approach to infants with excessive unexplained crying will allow the EP to diagnose the occasional severe illness and provide guidance to the caregivers.

**EPIDEMIOLOGY**

The prevalence of early excessive crying (e.g., >3 hours) in infants younger than 3 months has been estimated at 8% to 29%, but it may persist for months longer in up to 40% of these children. However, there is no accurate estimate of the incidence of excessive crying secondary to illness because almost every disease process can be accompanied by the symptom of crying. As infants grow and expand their repertoire for expressing specific needs, excessive crying is less frequently voiced as a primary complaint by caregivers.

**PATHOPHYSIOLOGY**

During the first few months of life, infants are expected to have variable periods of prolonged crying, which is normal behavior. However, crying is considered excessive when parents complain about it. Most paroxysmal episodes of crying have a behavioral etiology. In 1954 Wessel published his “rule of 3” for diagnosing colic: when an otherwise healthy infant between the ages of 3 weeks and 3 months cries more than 3 hours per day for more than 3 days per week. However, if organic pathology is to be identified, the EP must recognize...

</table>
that excessive crying has meaning and may be indicative of acute illness. In a study of 56 infants with an episode of excessive, prolonged crying without fever or cause identified by the parents, 61% had a serious final diagnosis. ¹⁰

**PRESENTING SIGNS AND SYMPTOMS**

The general appearance of the crying infant immediately helps the EP establish the severity of the illness (sick or not so sick?). A lethargic, ill-appearing, inconsolable infant mandates immediate consideration of sepsis, meningitis, increased intracranial pressure, or some other serious illness.

After the primary survey is complete and it is determined that no emergency intervention is indicated, the EP needs to elicit a comprehensive AMPLIFIED history (Box 16.2) from the primary caregiver. Clinical findings on the head-to-toe evaluation suggesting a potential cause of the excessive crying may include the following:

- Signs of head trauma, such as scalp contusions, ecchymoses and lacerations, hemotympanum, postauricular hematomas, or peri orbital ecchymoses
- A bulging fontanelle indicative of increased intracranial pressure
- A sunken anterior fontanelle consistent with dehydration
- Fluorescein uptake indicating corneal abrasions
- Retinal hemorrhages raising concern for serious abuse
- An erythematous and bulging tympanic membrane signifying otitis media

**BOX 16.2 The AMPLIFIED History for a Crying Infant or Toddler**

| Allergies                          | • Obstruction of the nares secondary to a foreign body |
| Medication (by mom or infant): Prescription, over the counter, natural remedies | • Oral thrush or mucosal ulcers in the oropharynx often seen with stomatitis |
| Past medical history               | • Exudative pharyngitis and fullness of the posterior pharynx suggesting peritonsillar or retropharyngeal abscesses |
|                                   | • Wheezing, rales, or rhonchi indicating a respiratory infection |
|                                   | • Palpation of a mass during the abdominal examination, which can be associated with pyloric stenosis, intussusception, or a tumor |
|                                   | • Diaper rash, anal fissure, or impacted stool on rectal examination |
| Immediate events (history of present illness and review of systems): OLD CAARS | • Scrotal swelling consistent with an incarcerated hernia or testicular torsion |
| Crying (when did the crying begin?) | • Extremity tenderness, edema, or bruising concerning for a possible fracture |
| Location: As the child develops a more expanded repertoire for communication and caretakers are able to intuit the child’s behavior, localization of pain is possible | • Erythema, induration, and tenderness suggesting a soft tissue infection (cellulitis or abscess) |
| Duration of crying                | • Hair tourniquet on a toe or finger |
| Characterization of crying: What does the cry sound like? Is it a cry of hunger, pain, or expression of a desire to be changed or cuddled? | • Rash with potentially life-threatening causes (e.g., petechiae, purpura) |
| Aggravating factors: What factors exacerbate the crying (e.g., holding the child, manipulating an extremity)? | • Alleviating factors: What factors alleviate the crying (e.g., feeding, caretaker contact)? |

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

A comprehensive history and systematic head-to-toe physical examination along with a period of ED observation are usually sufficient to differentiate acute illness or injury from a recurrent benign crying syndrome. It is important to remember that excessive crying may be the only behavioral change that the caregiver recognizes as an indicator of illness. Detection of subtle signs and symptoms will help identify high-acuity, low-frequency events. The practitioner should pay close attention to red flags in a young infant such as fever, failure to thrive, paradoxical irritability (crying with movement), vomiting, bloody stools, abnormal neurologic findings, and unexplained abnormal vital signs. A comprehensive differential diagnosis can be generated by using the head-to-toe memory tool (Fig. 16.2 and Box 16.3).

Allow the history, physical examination, and observed behavior of the infant to guide a stepwise approach to
**Fig. 16.2** Head-to-toe differential diagnosis.

**BOX 16.3 Differential Diagnosis of Crying (Head-to-Toe Memory Tool)**

**Head, Eyes, Ears, Nose, and Mouth**

*Head:* Meningitis, encephalitis, ventriculoperitoneal shunt malfunction or infection, closed head injury (skull fracture; epidural, subdural hematoma), cerebrovascular accident, tumor

*Eye:* Foreign body, corneal abrasion, glaucoma

*Ear:* Otitis media

*Nose:* Nasal congestion (distress in those <6 mo)

*Mouth:* Ingestion (drug toxicity such as carbon monoxide, methemoglobinemia), thrush, stomatitis

**Neck**

Mass, adenitis, torticollis, hyperthyroidism, hypothyroidism

**Chest**

*Chest wall:* Trauma

*Airway, lungs:* Pneumonia, bronchiolitis, hypoxia, hypercapnia, croup, tracheitis

*Cardiac:* Congenital heart disease, congestive heart failure, myocarditis, anomalous origin of the right coronary artery, supraventricular tachycardia

**Abdomen**

*Gastrointestinal tract:* Gastroesophageal reflux, aerophagia, pyloric stenosis, intussusception, malrotation with volvulus, inguinal hernia, gastroenteritis with dehydration, appendicitis, Hirschsprung disease, constipation, peritonitis

*Liver:* Inborn errors of metabolism

*Pancreas:* Hypoglycemia, diabetic ketoacidosis

*Kidney and urinary tract:* Electrolyte disorders, urinary tract obstruction, urinary tract infection, torsion of the testes or ovaries, hair tourniquet of the penis

*Adrenal:* Congenital adrenal hyperplasia

**Musculoskeletal**

Fracture or dislocation, osteomyelitis, septic arthritis, toxic synovitis, pain at injection site, pertussis vaccine reaction, hair tourniquet of a digit

**Skin**

Mastitis, omphalitis, burn, cellulitis, anal fissure, rash, insect or spider bite

**Neurologic**

Seizure activity, botulism

**Systemic**

Sepsis
diagnostic evaluation. A healthy-appearing infant who ceases crying before or soon after arrival at the ED rarely has a serious cause. An infant who continues to cry will require diagnostic testing directed by careful consideration of the potential differential diagnosis (Box 16.4). For example, suspicion of child abuse should prompt a funduscopic examination and consideration of radiographic studies, including a skeletal survey, computed tomography (CT) of the head, and CT of the abdomen and pelvis. Evaluate cardiac problems with continuous cardiac monitoring, a 12-lead electrocardiogram, a chest radiograph, and an echocardiogram as indicated. Confirm gastrointestinal pathology with selective radiographic studies such as screening supine and upright abdominal radiographs, ultrasound, upper gastrointestinal series, or judicious use of CT scanning. Evaluate for infectious causes with a chest radiograph, cerebrospinal fluid analysis, and urinalysis. Serum electrolytes, ammonia level, serum pH, and lactate levels are useful to screen for an inborn error of metabolism. Use C-reactive protein, the erythrocyte sedimentation rate, bone scanning, and magnetic resonance imaging to evaluate potential musculoskeletal pathologies.

**TREATMENT AND DISPOSITION**

The treatment plan and consultative services for excessive crying are determined by the underlying cause. An infant who ceases to cry and otherwise demonstrates no evidence of systemic illness may be discharged home with close follow-up. However, before discharge, carefully assess the caregiver’s capacity to continue caring for the infant while recognizing that admission of the infant may provide a needed respite. In addition, minimize the risk for abuse by confirming that an adequate support system is available. If discharged home, provide clear instructions to return with any progression of symptoms.

---

**ALTERED LEVEL OF CONSCIOUSNESS**

**PERSPECTIVE**

An infant or toddler with an altered level of consciousness may have a life-threatening illness that requires immediate recognition and treatment to prevent permanent central nervous system (CNS) dysfunction or death.

**EPIDEMIOLOGY**

An altered level of consciousness in this age group is caused by nonstructural causes (e.g., infection, metabolic abnormalities, toxin ingestion) or primary structural disease of the CNS (e.g., hemorrhage, tumors). Physical abuse is the leading cause of serious head injury in young children. Shaken baby syndrome most often involves children younger than 2 years and can easily be misdiagnosed.

**PATHOPHYSIOLOGY**

A normal level of consciousness requires proper function and communication of the cerebral cortex and reticular activating system. Normal neuronal activity involves a multifaceted communication of the cerebral cortex and reticular activating system. Normal neuronal activity involves a multifaceted communication of the cerebral cortex and reticular activating system. Normal neuronal activity involves a multifaceted communication of the cerebral cortex and reticular activating system. Normal neuronal activity involves a multifaceted communication of the cerebral cortex and reticular activating system. Normal neuronal activity involves a multifaceted communication of the cerebral cortex and reticular activating system.
Always direct the initial evaluation toward identifying potential life-threatening conditions such as hypoxia, hypotension, extremes of temperature, hypoglycemia, seizure activity, and increased intracranial pressure, which require immediate intervention. Once these issues have been excluded, the EP should perform an AMPLIFIEDD history (Box 16.5). Investigate the risk for accidental or nonaccidental trauma, infection, ingestion, or toxin exposure while identifying signs or symptoms suggestive of systemic disease. Interview all available caretakers and emergency medical service personnel.

Following the primary survey, a head-to-toe evaluation should be performed. The EP should:

- Pay close attention to the pupillary response, which generally remain intact with metabolic insults but may be absent with structural lesions, toxin exposure, or severe asphyxia.
- Note the eye position (e.g., deviation of conjugate gaze away from brainstem lesions and toward cerebral lesions).
- Identify abnormalities in the respiratory pattern that may reflect CNS insults or metabolic conditions such as metabolic acidosis.
- Evaluate motor strength, tone, and reflexes, and characterize activity that may be consistent with seizures or abnormal posturing.
- Look for signs of trauma, such as scalp contusions and lacerations, hemotympanum, postauricular or periorbital hematomas, retinal hemorrhages, cerebrospinal fluid otorrhea, and a bulging anterior fontanelle suggestive of increased intracranial pressure.
- Note odors suggesting inborn errors of metabolism or other metabolic disorders (e.g., the smell of acetone in a child with diabetic ketoacidosis).
- Identify physical findings that indicate systemic infections involving the CNS (e.g., vesicular or purpuric rashes).
- Identify signs of other systemic disorders that have a negative impact on mental status, such as intussusception (e.g., abdominal mass, blood in the stool), hepatic disorders (e.g., jaundice, icterus), or cardiopulmonary disease (e.g., hypoxia, rales, hepatomegaly).

A comprehensive differential diagnosis for alterations in consciousness in infants and toddlers can be generated with the head-to-toe memory tool (Box 16.6). Possible causes involve essentially every organ system. When the underlying cause of altered mental status is not obvious, a high level of suspicion should be maintained for abuse, accidental toxin ingestion or exposure, intussusception, infection, or nonconvulsive seizure activity.

Assess the ABCs of resuscitation—airway, breathing, and circulation—rapidly, initiate cardiorespiratory monitoring and pulse oximetry, and institute any necessary interventions immediately. Perform rapid bedside glucose testing as part of the primary survey. Consider antidotes for toxin exposure or poisoning (e.g., naloxone for opioid ingestion), and administer broad-spectrum antibiotics early if indicated.

Perform laboratory and radiographic testing via a systematic, comprehensive approach (Box 16.7). In a critically ill infant or toddler without a definitive diagnosis, routine testing for sepsis, trauma, and metabolic derangements should be supplemented with selective tests as dictated by progression of the clinical course, by the response to initial interventions, and by the history and physical findings.

If a definitive diagnosis is not rapidly apparent in a child with an altered level of consciousness, institute supportive care to assist ventilation and maintain adequate circulation, and treat potentially life-threatening conditions such as sepsis or electrolyte abnormalities. When a cause is diagnosed, appropriate treatment should follow. Unless an easily recognizable and reversible abnormality is present, all children with an altered level of consciousness should be admitted to a pediatric intensive care unit.
VOMITING

PERSPECTIVE

Vomiting in children is usually caused by a self-limited condition but may result from a severe, life-threatening illness. A systematic approach based on age-specific considerations is critical for making the appropriate diagnosis and treating infants and toddlers with vomiting. The EP should consider...
an expanded differential diagnosis in a child who comes to the ED with vomiting but no diarrheal illness.

**EPIDEMIOLOGY**

Episodes of acute gastroenteritis in children younger than 5 years lead to 2 to 3 million physician visits annually. The majority of these children have uneventful clinical courses.

**PATHOPHYSIOLOGY**

Vomiting is coordinated by the vomiting center in the reticular formation of the medulla. This vomiting center integrates and responds to afferent pathways from higher cortical centers in the brain and to visceral afferents from receptors in the gastrointestinal tract and other organs. Specifically, the chemoreceptor trigger zone in the floor of the fourth ventricle monitors chemical abnormalities in the blood and cerebrospinal fluid. A basic understanding of these major pathways is essential for developing diagnostic and therapeutic strategies for infants and toddlers with vomiting.

**PRESENTING SIGNS AND SYMPTOMS**

A review of the expansive list of potential causes of vomiting emphasizes the importance of developing an organized approach to achieve an accurate diagnosis. The EP should first elicit an AMPLIFIEDD history (Box 16.8) and perform a thorough head-to-toe physical examination focusing on the age of the infant or toddler. Evidence of bowel obstruction, peritonitis, and signs or symptoms suggestive of extraintestinal disease should be sought. Hydration status (Box 16.9) should be assessed. At the onset of the clinical encounter, the EP should clarify whether the child has had bilious or nonbilious vomiting because bilious emesis in infants implies intestinal obstruction until proved otherwise and requires immediate surgical consultation.

Appearance and age-appropriate behavior should be assessed because a decrease in activity or level of consciousness may indicate serious illness. A bulging fontanelle suggests increased intracranial pressure from potential causes.
such as meningitis, trauma, an intracranial mass, or intracranial bleeding. Retinal hemorrhages indicate nonaccidental trauma, and scleral icterus suggests hepatobiliary disease. An unusual odor may be the first clue to an inborn error of metabolism. Marked abdominal distention, peristaltic waves, increased bowel sounds, palpable masses, bloody stools, and guarding all point to an intraabdominal disorder. A thorough examination necessitates evaluation for torsion of the testes and the ambiguous genitalia associated with congenital adrenal hyperplasia. The skin should be examined for rashes indicative of an infectious cause. Unusual contusions or musculoskeletal injury may indicate nonaccidental trauma.

</table>

The list of potential causes of vomiting in infants is extensive but can be conveniently organized according to age-related categories (Table 16.3). Many serious medical conditions may be initially manifested as vomiting, such as sepsis, meningitis, urinary tract infection, and hepatitis. These conditions must be differentiated from emergency surgical conditions such as an incarcerated hernia, intussusception, and malrotation with volvulus. Intussusception is the most common cause of intestinal obstruction in children 3 months to 5 years of age, whereas appendicitis is the most common condition requiring surgical intervention.15,16

The large number of potential causes of vomiting makes routine laboratory and radiographic evaluation impractical. The history and physical findings should direct the choice of testing for each patient. For most common conditions, laboratory testing is not indicated. A bedside blood glucose measurement should be performed in any child with altered mental status. Serum electrolytes should be measured in children with dehydration requiring intravenous rehydration. A serum bicarbonate level lower than 17 mEq/L appears to be the most useful laboratory value for predicting the likelihood of 5% dehydration.17,18 Cerebrospinal fluid analysis should be performed if meningitis or encephalitis is suspected. Drug screening may be necessary to confirm an ingestion. Urinalysis, liver function tests, serum lipase, and ammonia measurements should be considered when the differential diagnosis is broadened.

Diagnostic imaging is also dictated by clinical findings. CT of the head should be performed for suspected closed-head injury, intracranial tumor, or hydrocephalus. Plain radiographs may be used to assess for bowel obstruction. An upper
gastrointestinal series is the preferred radiographic modality for diagnosing malrotation with volvulus. Diagnostic ultrasonography is the modality of choice for diagnosing intussusception. Ultrasonography and abdominal CT are used to investigate potential appendicitis when the diagnosis is in question. In children with equivocal findings for appendicitis, ultrasonography using the graded-compression technique should be performed, followed by focused abdominal CT if the ultrasonographic findings are normal. Similarly, implement protocols for appropriate use of ultrasonography and CT for evaluation of intraabdominal pathology such as trauma, an intraabdominal mass, or nephrolithiasis.

**TREATMENT**

Initial management of a vomiting infant or toddler should focus on hemodynamic stabilization. Persistent vomiting, severe dehydration, and electrolyte abnormalities necessitate treatment in parallel with other diagnostic testing. Rehydration is accomplished with 20-mL/kg intravenous boluses of isotonic saline, repeated as necessary. Additional treatment should be directed toward the underlying cause. Immediately consult a surgeon for infants with bilious vomiting. Malrotation with volvulus is a surgical emergency requiring rapid response to prevent infarction of the bowel. Timely surgical consultation is also the standard of care for other conditions such as peritonitis and incarcerated hernia. In some cases the radiologist may successfully reduce the intussuscepted bowel with an air or contrast enema, although surgical backup is required for potential complications or treatment failure. Decompression with nasogastric suctioning is indicated for children with ileus or bowel obstruction.

Administration of an antiemetic may serve as a successful adjunct to suppress vomiting and allow oral rehydration. Intravenous and oral ondansetron (a selective serotonin [5-HT3] receptor antagonist) has been used successfully in the ED for infants and children with vomiting secondary to gastroenteritis.

Oral rehydration therapy should be administered to children with mild to moderate dehydration as a result of gastroenteritis. A metaanalysis of randomized control trials involving 1545 children younger than 15 years concluded that rehydration by the oral or nasogastric route is as effective if not better than intravenous rehydration.

**DISPOSITION**

An infant or toddler with a self-limited condition and no evidence of systemic illness or dehydration can be discharged. Provide clear plans for follow-up and instructions for outpatient oral rehydration to the parents or caregiver. Always confirm that the caretaker understands the need to return to the ED if the illness progresses.

Infants or children with persistent vomiting, abnormal electrolyte values, or a more complex diagnosis requiring further medical or surgical management should be admitted to the hospital.

**PARENT TEACHING TIPS**

**Infant or Toddler in the Emergency Department**

Confirm that parents understand the diagnosis, treatment, followup plans, and any symptoms that warrant immediate return to the emergency department. Reinforce that parents are always welcome to return to the ED with any concern.

Child with a Fever

Jana L. Anderson, Christopher S. Kiefer, and James E. Colletti

17

KEY POINTS

- A fever is defined as a temperature of 38.0° C (100.4° F) or higher measured rectally.
- Response to antipyretics is not a predictor of the presence of bacterial illness and therefore should not influence clinical decision making.
- The diagnostic evaluation of a febrile child is based on clinical findings, immunization status, and age of the child.
- The peripheral white blood cell count is unreliable in determining the presence or absence of bacterial illness and should not guide diagnostic and treatment decisions.

PERSPECTIVE

Developing an accurate diagnostic impression, performing an appropriate work-up, and determining treatment and disposition for a febrile infant or child is not always a straightforward process. The diagnostic work-up varies dramatically based on the age of the child, clinical appearance, physical examination, maternal risk factors, and immunization status.

Fever is the most common chief complaint in children younger than 3 years seen in the emergency department (ED) (see Facts and Formulas box). Fever is defined as an elevation in temperature to 38.0° C (100.4° F) or higher. In young children, particularly those younger than 2 years, the temperature should be taken rectally because other methods such as tympanic and axillary are not as reliable or accurate.1 Parental report of fever determined by touch is likely to be accurate regarding the presence of a fever.2 A common misconception is that bundling a baby can account for an elevation in core temperature, but it cannot.3 More than 20% of fevers seen in the ED will be fevers without a source and require risk stratification based on the child’s age, appearance, and immunization status.

Infants are at particularly high risk for serious bacterial illnesses because of their minimal signs and symptoms, lack of immunity, maternal birth canal exposure, and difficulty in mounting a response to infections. To deal with this increased risk for infection, multiple protocols to evaluate a febrile infant have been developed (Box 17.1). As a general consensus, infants younger than 28 days with a temperature of 38.0° C should undergo a full sepsis evaluation, parenteral administration of antibiotics, and admission to the hospital.4 A full sepsis evaluation includes a complete blood count (CBC) with differential, blood culture, and a catheterized urine sample sent for urinalysis, Gram stain, and culture. If symptoms are present, stool studies or a chest radiograph should be performed. A lumbar puncture with cell count and differential, Gram stain, and culture should be obtained. Antibiotics recommended are ampicillin, 50 mg/kg, and cefotaxime, 50 mg/kg. Ceftriaxone is not used in the neonatal period because of possible disconjugation of bilirubin. Neonatal herpes should also be considered as a cause of the fever, particularly in infants younger than 2 weeks. Frequently, the mother’s history of maternal herpes is not known, nor does the child have any physical findings. If there is any concern, herpes polymerase chain reaction should be performed on cerebrospinal fluid and the child should be administered acyclovir (20 mg/kg). Overall, well-appearing febrile neonates have a 7% likelihood of having a serious bacterial infection, with the most common being a urinary tract infection.5–7

Infants 28 days to 2 to 3 months of age may be risk-stratified with the febrile infant protocol to help guide the evaluation of fever (Figs. 17.1 and 17.2). Many physicians use an age cutoff of 60 days or less to perform a full sepsis evaluation, although some physicians still perform a full sepsis evaluation in children up to 90 days of age.8 These practice variations are seen in different settings: ED-based evaluation versus office-based evaluation and academic settings versus those in private practice.9 If a young infant meets the low-risk criteria outlined in Box 17.1, the physician may send the infant home with no antibiotics and follow-up the next day (note that the Boston criteria do recommend antibiotic administration). If the physician has any reservation about the ability of the caregivers to follow-up or any social concerns, one should err on the side of caution and admit the child to the hospital. If the infant does not fall into the low-risk criteria outlined, parenteral antibiotics should be administered and the child admitted to the hospital. Parenteral antibiotics should be given only if a lumbar puncture has been performed. Antibiotics used in this age group are ceftriaxone, 50 mg/kg intravenously or intramuscularly, or cefotaxime, 50 mg/kg intravenously.
Approach to febrile infants 0 to 28 days of age or through days of temperature, age, and possible progression of OB to meningitis. In 1987, the Haemophilus influenzae type B (Hib) vaccine was introduced and dramatically reduced the prevalence of OB secondary to Hib to the point of no longer being clinically pertinent.12 The heptavalent pneumococcal conjugated vaccine (PCV-7) was introduced in the United States in 2000 and has recently been expanded to thirteen valent (PCV-13). PCV-13 is aimed at the most invasive strains of S. pneumoniae and is administered at 2, 4, 6, and 12 to 15 months. After one dose, the vaccine has 90% efficacy against vaccine serotypes. Although the recommended vaccination schedule for the pneumococcal vaccine includes four immunizations, it has been reported that two vaccinations induce satisfactory antibody responses and may therefore be protective.13 It is thought that herd immunity may provide protection for older adults and unimmunized children.14-16

Lee et al. determined that at rates of pneumococcal bacteremia greater than 1.5%, obtaining a CBC, performing blood cultures, and administering antibiotics empirically was cost-effective.17 Conversely, if the rate of pneumococcal bacteremia was less than 0.5%, strategies using empiric testing and antibiotics would no longer be cost-effective. Since the work of Lee et al. several investigations have determined the overall frequency of pneumococcal bacteremia to be well below 1%.14,18,19 The rate of bacteremia may be low enough to support the evolving practice of not drawing blood for routine CBC and blood cultures in previously healthy febrile children between 2 and 36 months of age who have received at least one PCV-7 vaccination.20 Evidence is mounting that the bacteremia rate and particularly the pneumococcal bacteremia rate have declined to the extent that empiric testing and treatment may no longer be necessary.

**PATHOPHYSIOLOGY**

Fever is the host’s adaptive response to an invading microorganism. The microorganism comes in contact with cells of the immune system, including macrophages and leukocytes, and such contact leads to the release of various cytokines, most notably interleukin-1, tumor necrosis factor, and interleukin-6. These cytokines circulate and come in contact

**Philadelphia Criteria**

Infants 29 through 56 days of age with temperatures of 38.2°C or higher

- Temperature > 38.0 °C
- Age less than 28 days or Age 28-90 days with high-risk factors or ill appearance
- Blood: complete blood count with differential, blood culture
- Urine: catheterized sample for urinalysis, Gram stain, culture
- Cerebrospinal fluid: cell count and differential, culture, protein, glucose
- Herpes PCR if any pleocytosis
- Chest x-ray if any respiratory symptoms

Administer antibiotic/antiviral medications

- Less than 28 days: ampicillin, 50 mg/kg/dose, and cefotaxime, 50 mg/kg/dose IV
- 28-90 days: ceftriaxone, 50 mg/kg/dose IV or IM, or cefotaxime, 50 mg/kg/dose IV
- If any concern for herpes: acyclovir, 20 mg/kg/dose IV

Admit to hospital

---

with neuronal cell groups around the edges of the brain’s ventricular system. Prostaglandin E\(_2\) is then released and binds to receptors on neurons in the hypothalamus and brainstem, which leads to upregulation of the hypothalamic thermostatic set-point.\(^{23,24}\) Once the thermoregulatory center is reset, a higher body temperature is maintained through various mechanisms such as cutaneous vasoconstriction and shivering. The febrile response is not fully developed in young infants, and fever or even hypothermia may occur in response to infection. The physiologic limit of thermoregulation is estimated to be 41.1° C (106° F). According to McCarthy, children with a fever of this degree have a high rate of central nervous system insult.\(^1\)

**Fig. 17.3** Approach to children 3 to 36 months of age with fever and no obvious source. WBC, White blood cell. (Adapted from Baraff LJ. Management of fever without source in infants and children. Ann Emerg Med 2000;36:605.)

**Facts and Formulas**

- Fever: for ages 0 to 2 months, a temperature of 38.0° C or higher measured rectally; for ages 2 to 36 months, a temperature of 39° C or higher measured rectally
- Fever without a source: acute febrile illness without localizing signs or symptoms despite a careful history and physical examination
- Bacteremia: presence of bacteria in the bloodstream
- Occult bacteremia: presence of bacteria in the bloodstream of a febrile child who may not appear particularly sick and has no apparent other source of infection
- Serious bacterial illness: accounts for 2% to 4% of fevers. Examples include pneumonia, cellulitis, septic arthritis, osteomyelitis, urinary tract infection, meningitis, and sepsis\(^{21,22}\)

**Presenting Signs and Symptoms**

When evaluating a febrile child, the clinician must obtain key information from the history and physical examination (Box 17.2 and see the Documentation box). According to McCarthy et al., the sensitivity of clinical evaluation in an infant younger than 3 months and between 3 and 36 months of age is 78% and 89% to 92%, respectively.\(^{1,25}\) After the history and physical examination, the source of fever remains inapparent in 20% of febrile children.\(^{30,27}\)

**Differential Diagnosis**

The differential diagnosis of acute pediatric fever is vast (Box 17.3). It is imperative to become familiar with the myriad causes of pediatric fever. The defining characteristics of each diagnosis can be found elsewhere in this text.

**Diagnostic Testing**

Diagnostic evaluation is based on the patient’s age group.\(^{11,26,28}\) Figures 17.4 and 17.5 outline the indications for other common diagnostic tests in children with fever.\(^{29,33}\)

**Urinalysis and Culture**

Occult urinary tract infections occur in 2% to 3% of male infants younger than 1 year. Most of these infections occur in uncircumcised boys and infants younger than 6 months. Occult urinary tract infections occur in 8% to 9% of female children younger than 2 years.\(^{26}\) Girls between 2 months and 2 years of age can be risk-stratified for urinary
tract infection (see Fig. 17.4) with a sensitivity of 95% and specificity of 31%.

Urine can be collected for testing in several ways. Bag collection is a noninvasive, convenient method, but it is not recommended because of a false-positive rate of nearly 85%. Percutaneous bladder aspiration is another approach, but because this method is more invasive, it is also not the preferred approach except in male infants with severe phimosis. Urethral catheterization is generally regarded as the preferred method of obtaining urine, and its sensitivity and specificity are reported to be 95% and 99%, respectively. Once a catheterized urine specimen has been obtained, it should be sent for testing. A negative urinalysis and a negative Gram stain are not sufficient to exclude a urinary tract infection because up to 50% of patients with a urinary tract infection documented by urine culture have a false-negative urinalysis result. Therefore, it is important to obtain a urine culture in conjunction with urinalysis and a Gram stain.

The utility of an elevated peripheral white blood cell count in evaluating a febrile child is debatable. It has been shown to be an inaccurate screen for bacteremia and meningitis in febrile infants. The decision to administer antibiotics, to perform or withhold lumbar puncture, or to admit or discharge the patient should not be based solely on interpretation of the white blood cell count. Several criticisms of this study have been raised, including the high degree of interobserver variability in interpretation of chest radiographs, failure to perform a peripheral white blood cell count in more than half the infants with a temperature of 38°C or higher, and performance of the majority of clinical assessments by physicians in training rather than by faculty physicians. Nonetheless, data in the literature are sufficient to support the policy of the American College of Emergency Physicians, which outlines the indications for obtaining a chest radiograph in children younger than 3 years (see Fig. 17.5).

**RADIOGRAPHY**
Deciding when to perform a chest radiograph in a febrile child can be challenging. Nearly 7% of all febrile children younger than 2 years with a temperature higher than 38°C have pneumonia. In an investigation by Bachur et al., occult pneumonia (defined as the presence of an infiltrate on a chest radiograph in a child without clear clinical evidence of pneumonia) was discovered in up to 26% of febrile children without a source and with a white blood cell count higher than 20,000/mm³. Several criticisms of this study have been raised, including the high degree of interobserver variability in interpretation of chest radiographs, failure to perform a peripheral white blood cell count in more than half the infants with a temperature of 38°C or higher, and performance of the majority of clinical assessments by physicians in training rather than by faculty physicians. Nonetheless, data in the literature are sufficient to support the policy of the American College of Emergency Physicians, which outlines the indications for obtaining a chest radiograph in children younger than 3 years (see Fig. 17.5).

**TREATMENT AND DISPOSITION**
The clinician should administer appropriate dose of antipyretic early in the evaluation of a febrile child (acetaminophen, 15 mg/kg, or ibuprofen, 10 mg/kg). The response to antipyretics is not a useful determinant of the presence of bacterial illness and should not influence clinical decision making. Treatment and disposition of infants younger than 90 days are outlined in Figures 17.1 and 17.2. For infants managed on an outpatient basis, tests performed in the ED occasionally come back positive after the patient has been discharged. If blood cultures are positive, the child should be admitted for evaluation of sepsis and parenteral administration of antibiotics, especially in the setting of persistent fever. For positive urine cultures, the patient’s symptoms affect disposition. In the setting of persistent fever, the child should be admitted to the hospital for evaluation of sepsis and parenteral administration of antibiotics. In an afebrile and well-appearing child, outpatient management with oral...

Female patients with 2 or more of the following identified:
- Age younger than 1 year
- Caucasian
- Temperature > 39.0° C
- Fever duration > 2 days
- Lack of obvious source on history or examination

Obtain catheterized urine for urinalysis and culture

Child younger than 3 months with acute respiratory illness

Child older than 3 months with temperature > 39° C and any of the following:
- Tachypnea
- Wheezes
- Rhonchi
- Retractions
- Nasal flaring
- Abnormal breath sounds
- Cough
- Pulse oximetry < 95% on room air

Obtain chest x-ray
### Key Historical Findings in the Evaluation of a Febrile Infant or Child

- **Age of the child**
- **Height and duration of the fever**
- **Method of obtaining the temperature**
- **Use, timing, and dose of antipyretics administered**

#### Caretaker’s Report of Well-Being

- **Level of activity**
- **Consolability**
- **Irritability**
- **Lethargy**
- **Playing**
- **Smiling**
- **Eating**
- **Pitch of cry (a high-pitched cry may be indicative of a central nervous system infection)**

#### Hydration Status

- **Fluid intake**
- **Urinary output**

#### Respiratory Symptoms

- **Cough**
- **Work of breathing**
- **Nasal flaring**
- **Intercostal retractions**
- **Grunting**

#### Gastrointestinal Symptoms

- **Vomiting**
- **Diarrhea**
- **Abdominal pain**

#### Urinary Symptoms

- **Dysuria**
- **Frequency**
- **Urgency**
- **Hematuria**

#### Ear, Nose, and Throat Symptoms

- **Earache**
- **Sore throat**

#### Dermatologic Symptoms

- **Rash**

#### Past Medical History

- **Birth history**
- **Length of gestation, mode of delivery, infections during pregnancy, antibiotics during pregnancy, mother’s group B Streptococcus status**
- **Immunization status**
- **Underlying medical illnesses**
- **Previous hospitalizations**

#### Social History

- **Contact with ill persons**
- **Day care**
- **Recent travel**

---

### PATIENT TEACHING TIPS

**Explain to the caretaker that a fever in the absence of a serious bacterial illness is not harmful.**

**Explain how to take a temperature properly.**

It is best to take the infant’s or toddler’s temperature rectally.

**Hold the child belly down on your lap.**

Lubricate the thermometer with water-soluble jelly.

**Spread the buttocks and insert the lubricated thermometer approximately 1 inch into the rectum.**

#### Antipyretics

**Explain that many formulations of acetaminophen are available and that parents should base the dose of acetaminophen or ibuprofen on the weight of the child.**

---

### TIPS AND TRICKS

**Perform most of the physical examination with the child in the parent’s lap.**

**Begin with less noxious components of the examination and proceed gradually to those that may be upsetting to the child (i.e., the pulmonary, cardiac, and neurologic components of the physical examination are performed before the abdominal, tympanic, and pharyngeal components).**

**Attempt to calm a fussy or uncooperative child through feeding, use of antipyretics, or aid of the child life team.**

For an apprehensive toddler, demonstrate examination of the particular body part on the parent holding the child before performing it on the child.

---

### RED FLAGS

Meningeal signs are not highly reliable in the first 12 to 16 months of life.

**Remember to document the child’s general appearance carefully.**

Do not overly rely on the white blood cell count to determine the extent of evaluation in an infant.

In cases in which the reliability of the caregiver is in question, it is safer to admit the patient to the hospital. Indicators of unreliable follow-up are as follows:

- Young parents
- Parents without access to transportation
- Caretakers who do not believe that their child is ill

Close (next day) and reliable follow-up is important.

Whenever possible, consult with the infant’s pediatrician to obtain information regarding parental reliability, to discuss evaluation, and to arrange close follow-up.

In cases in which follow-up is uncertain, extensive evaluation and hospital admission are reasonable.
antibiotics is a reasonable plan. Follow-up studies, including repeated cultures of urine and blood, as well as voiding cystourethrography and renal ultrasound scanning, should be arranged.

In children 2 to 3 months to 36 months of age, the clinical impression and the patient’s temperature guide management decisions. This approach is outlined in Figure 17.3. Toxic-appearing children with fever should be admitted to the hospital and treated. Well-appearing children with a temperature lower than 39°C should be treated with antipyretics and may be discharged. Laboratory testing should be withheld in these patients, and parents should be provided with instructions to return if their children have persistent fever or their condition deteriorates. In a well-appearing child with a temperature higher than 39°C, the guidelines for urine testing and chest radiography outlined in Figures 17.4 and 17.5 should be followed. Regardless of the management approach chosen, close outpatient follow-up should be ensured, and the patient’s parents should be provided with clear instructions that describe when to return to the ED for reevaluation. Box 17.4 provides information to provide to the parent. Fever is a common complaint in the ED in children younger than 36 months. The Hib and pneumococcal vaccines have reduced the incidence of OB and thus have altered the evaluation and management of febrile infants and children. This remains an evolving process, with the rate and degree of evolution yet to be determined.

**Box 17.4 Information for the Parent: Goals for Care at Home**

1. Reduce the temperature
   - Appropriate dosing and intervals of administration of antipyretics based on information written on the label and the child’s weight
2. Maintain hydration
   - Persistent or worsening vomiting and/or diarrhea
   - Signs of dehydration
   - Decreased urine output or tears
   - Sunken eyes
   - Dry diapers
3. Monitor for worsening or life-threatening illness and return immediately to the emergency department for:
   - Changes in level of alertness (lethargy, irritability, or inconsolability)
   - Signs of increased work of breathing (grunting; retracting; nasal flaring; rapid, shallow, or difficult respirations)
   - Bilious vomiting
   - Seizure
   - Purple or red rash
   - Persistent headache

INTRODUCTION

Children are often brought to the emergency department with rashes ranging from the inconsequential (insect bites) to life-threatening emergencies (meningococemia). When evaluating a rash, physicians should be systematic in the creation of an appropriate differential diagnosis, with early identification of possible life-threatening dermatologic conditions. Assessment of the distribution, morphology, and quality of the rash is of paramount importance. Detailed historical data regarding systemic symptoms and antecedent events are required. Please refer to Chapter 191 for the approach to undifferentiated rash. This chapter addresses dermatologic conditions most commonly diagnosed in pediatric patients.

PATHOPHYSIOLOGY

The pathophysiology of rash in pediatric patients is broad and depends on the inciting etiologic agent. In this population, viral illnesses are most common. However, vasculitic reactions, primary and secondary bacterial infections, fungal infections, and chronic inflammatory states provide additional causes.

PRESENTING SIGNS AND SYMPTOMS

CLASSIC EXANTHEMS AND VIRAL RASHES

Historically, six infectious exanthems were originally described: measles or rubeola (first), scarlet fever (second), rubella (third), Dukes disease (fourth), erythema infectiosum (fifth), and exanthema subitum or roseola infantum (sixth). The majority of childhood exanthems are nonspecific and cannot be accurately assigned to a discrete etiologic diagnosis. These exanthems are typically self-limited and resolve spontaneously within a week. Table 18.1 details these classic exanthems and viral rashes.

Measles

Measles is rarely seen in developed countries because of the widespread use of vaccination. However, measles continues to affect the populations of developing countries. In 1997 it was the sixth leading cause of death worldwide; it is still the leading cause of blindness in African children. The causative agent of measles is paramyxovirus, which has an incubation period of 7 to 12 days, and infection occurs most commonly in winter and spring. Measles is contagious 3 days before and 5 days following onset of the rash. It begins with a prodrome of gradually increasing fevers (>40° C), headache, coryza, dry hacking cough, and an impressive bilateral conjunctivitis (the three C’s). The prodrome occurs 2 to 4 days before the rash. Koplik spots are clustered, white lesions (“grains of salt on a wet background”) that may appear on the buccal mucosa opposite the second molars during the prodromal period (Fig. 18.1). They are pathognomonic if present. The erythematous, nonpruritic, maculopapular rash first appears at the hairline and behind the ears and then spreads inferiorly. As the rash involves the trunk and extremities, the discrete macules coalesce. After 1 week the rash fades. Diagnosis of measles is typically made clinically; however, laboratory diagnosis via serologic assay is available. Treatment of measles is supportive. Administration of vitamin A is associated with a reduction in risk for mortality in children younger than 2 years, as well as a reduction in postmeasles pneumonia complications. Complications of measles include...
Scarlet Fever
Scarlet fever, an exotoxin-mediated illness caused by infection with Streptococcus pyogenes, occurs primarily in children younger than 10 years. Scarlet fever is most often associated with streptococcal tonsillopharyngitis, although it can be seen following other streptococcal infections. Its incidence is highest during the late fall to late winter, and the incubation period is 2 to 5 days. Symptoms include an abrupt onset of fever, headache, malaise, and odynophagia with occasional vomiting and abdominal pain. This is followed by the appearance of a strawberry tongue and a bright red enanthem (oral rash) on the soft palate and uvula. These punctate, erythematous macules are called palatal petechiae or Forchheimer spots. The rash, which follows the fever by 1 to 2 days, is a generalized erythroderma with scattered pinpoint petechiae, with a sandpaper-like texture. Capillary fragility causes petechiae in the flexural surfaces (Pastia lines), and facial flushing with circumoral pallor is often apparent. The palms and soles are typically spared. The exanthem typically resolves in 5 days, followed 2 weeks later by postexanthematous desquamation, especially of the palms and soles. The diagnosis is made clinically but can be confirmed by streptococcus-positive throat culture. Penicillin remains the treatment of choice to prevent local supplicative complications and acute rheumatic fever. Additional complications are rare but include sepsis, acute glomerulonephritis, pneumonia, pericarditis, hepatitis, otitis media, meningitis, and toxic shock syndrome (TSS) (Fig. 18.2).

Rubella
Rubella is a relatively mild illness caused by Rubivirus that is accompanied by a maculopapular rash. The incubation period is 12 to 23 days, with the period of infectivity extending from a few days before until 7 days following onset of the rash. Rubella occurs most commonly in late winter and early spring. The prodrome is mild, if present, and consists of Koplik spots, high fever, cough, coryza, and conjunctivitis. Forchheimer spots. The rash typically resolves in 3 to 4 days. The prodrome is common in adolescents and adults but is often absent in younger children. Other clinical findings include posterior cervical and occipital lymphadenopathy, Forchheimer spots, arthralgia, and neutropenia. The diagnosis is made clinically but serologic tests are available. Treatment of rubella is supportive. However, patients must avoid pregnant women (first 20 weeks of gestation) to prevent spontaneous abortion or congenital rubella syndrome. Complications of rubella include arthritis, encephalitis, and thrombocytopenia.

SECTION II - SPECIAL CONSIDERATIONS IN THE PEDIATRIC PATIENT

150
the child a “slapped cheek” or sunburned appearance. This rash lasts 1 to 4 days and then progresses to a more generalized rash with a lacy reticular pattern, most prominent on the extremity extensor surfaces. The rash may then wax and wane for a month, with various stimuli increasing its intensity. Once the rash appears, children are no longer infectious.1 The diagnosis is made clinically, but serologic tests can be used. Treatment of erythema infectiosum is supportive, but parents must keep infected children away from pregnant women and those with hemolytic anemia. High-risk groups may be treated with intravenous immune globulin (IVIG).15 Complications are rare but include symmetric arthritis of the hands, wrists, or knees and intrauterine infection and fetal death if the infection occurs during the first half of pregnancy. Children with hemolytic anemia and hemoglobinopathy (particularly sickle cell disease) are prone to transient aplastic crisis when infected with parvovirus.18-21

Roseola Infantum (Exanthema Subitum)
Roseola is the most common viral exanthem in children younger than 3 years. It is called baby measles or 3-day fever, and the causative agents are human herpesviruses 6 and 7.22,23 Roseola has an incubation period of 5 to 15 days.15,24 It is characterized by high fever for 2 to 5 days in an otherwise well-appearing child. Following dissipation of the fever, a blanching, evanescent, pink maculopapular exanthem develops on the neck and trunk. The rash typically lasts approximately 1 to 2 days. Associated symptoms include mild coryza, cough, otitis media, headache, periorbital edema, and posterior cervical lymphadenopathy.23-25 An enanthem of red papules (Nagayama spots) may be seen on the mucosa of the soft palate and uvula.23,25 The diagnosis is made clinically and treatment is supportive.15,24,26 Febrile seizures are a common complication. Other complications are uncommon but include thrombocytopenia, hepatitis, and encephalitis.15,24,27

Varicella (Chickenpox)
The incidence of varicella has decreased 90% in the last 20 years with routine vaccinations.28 Chickenpox, caused by varicella-zoster virus, is highly contagious, with a peak incidence in late winter and spring.29,30 Children 2 to 8 years of age are primarily affected. After an incubation period of 10 to 21 days, the prodrome begins with malaise, low-grade fever, cough, coryza, anorexia, sore throat, and headache.30,31 Within 1 to 2 days the skin eruption begins on the trunk and then spreads over the next week to the face (including the mucous membranes) and extremities (with sparing of the palms and soles). The lesions begin as red macules that quickly progress to discrete vesicles on an erythematous base (Fig. 18.3). The vesicles (“dew drops on a rose petal”) rapidly evolve into pustules, which umbilicate and crust over in 5 to 10 days.1,30 The infectivity period begins several days before onset of the rash and lasts until all the lesions are completely crusted.15 The diagnosis is made clinically; however, a Tzanck preparation demonstrating multinucleated giant cells or other viral assays can be used for confirmation.15,30 Treatment is usually supportive, with management of constitutional symptoms and pruritus and prevention of secondary infection.15,30 Wet dressings, soothing baths, calamine lotion, and
myocarditis, pleurodynia, parotitis, hepatitis, pancreatitis, and encephalitis. Hand-Foot-and-Mouth Disease is caused by Coxsackie A virus and enterovirus 71. It is characterized by oral vesicles, followed by vesicles on the hands and feet and may also include the buttocks. The incubation period is 3 to 6 days. Patients are highly contagious 2 days before and 2 days following onset of the eruption. There is a brief prodrome consisting of low-grade fever, malaise, anorexia, and odynophagia. The oral lesions begin as small red macules that evolve into vesicles measuring 2 to 20 mm. These vesicles rupture rapidly and leave painful erosions. Children often refuse to eat or drink because of pain, and dehydration is a potential complication. Rare complications include myocarditis, pneumonia, meningoencephalitis, and aseptic meningitis. Infection during the first trimester of pregnancy may result in spontaneous abortion.

Skin and Soft Tissue Infections: These infections represent the most common bacterial, fungal, and viral infections of childhood. Table 18.2 details these pediatric skin and soft tissue infections.
**Impetigo**

Impetigo is a superficial bacterial skin infection typically caused by *S. aureus* or *S. pyogenes* and is the most common cutaneous infection in children.\(^1\)\(^,\)\(^2\)\(^,\)\(^3\)\(^2\)\(^,\)\(^4\)\(^,\)\(^5\) Impetigo is most prevalent in children younger than 6 years and typically occurs in late summer and early fall secondary to microscopic breaks in the epidermal barrier.\(^1\)\(^,\)\(^2\)\(^,\)\(^3\)\(^2\)\(^,\)\(^4\)\(^\)\(^,\)\(^5\) Additional contributing factors include warm humid climates, overcrowding, and poor hygiene.\(^1\)\(^,\)\(^2\) Impetigo is highly communicable.\(^2\)\(^,\)\(^3\)\(^\)\(^,\)\(^4\) Variants of impetigo include bullous impetigo and impetigo contagiosa. Bullous impetigo is seen most often in neonates and is caused by *S. aureus* phage group II. The lesions of bullous impetigo commonly occur in the periumbilical or perineal region in neonates and on the extremities in older children. The lesions are flaccid, thin-walled bullae that when ruptured leave shiny, rounded erythematous erosions with peeling edges ("coin lesions").\(^3\)\(^,\)\(^4\)\(^,\)\(^5\) Associated lymphadenopathy is rare and the Nikolsky sign is negative. Impetigo contagiosa is the most common variant and is caused by *S. aureus* or group A β-hemolytic streptococci.\(^3\)\(^,\)\(^4\) The rash begins as small painless erythematous macules, commonly near the nose and mouth, which then progress to small vesicles and pustules with erythematous margins. These lesions rupture easily and release a serous fluid, which dries to form a honey-colored crust.\(^3\)\(^,\)\(^4\)\(^,\)\(^5\) Associated regional lymphadenopathy is common. Topical antibiotics, such as 2% mupirocin, are often effective for limited infections.\(^3\)\(^,\)\(^4\)\(^,\)\(^5\) However, extensive lesions may be treated with 10 days of oral antibiotics directed at *Staphylococcus* and *Streptococcus*. Suggested antibiotics include cephalexin, amoxicillin-clavulanate, azithromycin,
Erysipelas

Erysipelas is a distinctive form of cellulitis that affects mainly infants, young children, and the elderly. It is caused by group A streptococci. Erysipelas affects only the upper dermis, whereas the more classic cellulitis also involves the deep dermis and subcutaneous fat. Erysipelas occurs most commonly on the face or lower extremities, although any area of the body may be affected. The lesions appear as warm, tender, shiny, erythematous plaques with raised and sharply demarcated borders. Rapid spread is the rule, and lesion blistersing can occur. Associated signs and symptoms include high fever, chills, and anorexia. The diagnosis is made clinically. Treatment with penicillin plus clindamycin is recommended, and the combination may be associated with better outcomes than monotherapy.

Tinea

Tinea is a general term used to describe a collection of skin infections caused by fungi. Tinea capitis is rarely seen past adolescence, whereas tinea pedis and cruris are usually seen in adolescents and adults. Tinea corporis produces annular, erythematous, pruritic patches with a scaly leading edge. Treatment of tinea corporis, cruris, and pedis includes topical antifungal preparations such as miconazole or clotrimazole for 2 to 4 weeks. Tinea capitis is characterized by scaly discrete patches of alopecia. It is the most common dermatophytosis of childhood. Most cases occur in children 4 to 7 years old, with a predilection for African Americans. Clinical findings vary from scaling and patchy hair loss to pruritic papules, pustules, and crusting. Occipital and posterior cervical adenopathy is usually present. Additionally, “black dots,” or short broken-off hairs, may be seen at the scalp surface. A kerion (tender boggy abscess devoid of hair) occasionally develops as a severe inflammatory reaction to the fungus. A Wood lamp can aid in the diagnosis of tinea capitis. Hairs infected with Microsporum will fluoresce blue-green. Wood lamp evaluation is not helpful in the diagnosis of tinea infections on hairless skin. Alternatively, direct KOH microscopy of skin scrapings can also be used for diagnosis. Treatment of tinea capitis consists of 6 to 8 weeks of oral griseofulvin and a selenium sulfide shampoo twice weekly. Treatment with griseofulvin mandates monitoring of liver function. Alternative treatment regimens consisting of terbinafine, itraconazole, and fluconazole may also be effective. Contaminated hairbrushes, towels, pillows, and hats should be disinfected.

Molluscum Contagiosum

Molluscum is a common childhood viral infection of the skin characterized by umbilicated papules. It is caused by a poxvirus and can occur at any age but is most common in young children and those with impaired cellular immunity. Molluscum is contagious and seen frequently in swimmers, wrestlers, and sexually active persons. Those with atopic dermatitis and immunosuppression are especially susceptible. The incubation period ranges from 2 to 8 weeks. The lesions are discrete skin-colored, dome-shaped papules 2 to 5 mm in diameter and usually umbilicated. The lesions are typically painless and nonpruritic. They occur (alone or in groups) on
Atopic Dermatitis (AD), commonly referred to as eczema, is an inflammatory skin condition characterized by pruritus, erythema, vesicles, and scales. Once chronic, AD can also appear lichenified and hyperpigmented.1,45 AD is more commonly diagnosed in children with a family history of atopy (allergic rhinitis, conjunctivitis, asthma, and atopic dermatitis).1 Nearly 95% of patients in whom eczema is diagnosed by 5 years of age.1 The lifetime prevalence of AD is approximately 17%.53 Although the exact cause is unknown, eczematous skin is postulated to have a decrease in skin lipids and thus altered water-binding capacity. This leads to marked skin dehydration, pruritus, and scratching, which results in the characteristic skin lesions.53 In young infants, scaly, erythematous papules, patches, or vesicles commonly erupt on the face, the extensor surfaces of the legs, and less commonly the trunk. Approximately 50% of young infants in whom eczema is diagnosed have complete resolution of symptoms by 3 years of age. In older children, eczematous lesions tend to be found in the flexural surfaces and the neck. These lesions appear scaly and erythematous, often with crusts, excoriation, and lichenification. Of note, eczematous lesions in dark-skinned individuals frequently occur on extensor rather than flexural surfaces and are more papular and hyperpigmented in appearance. Treatment of AD includes behavioral changes, emollients, topical corticosteroids, and antihistamines.1,53 Fragrances and bubble baths should be avoided. Mild, unscented moisturizing soaps (Dove, Aveeno) are preferred. Irritants such as overly hot water, synthetic fabrics, wool, stuffed toys, bleach, and fabric softeners should be avoided. Long-sleeved cotton shirts can protect the skin. Patients with AD should apply emollients (Aquaphor, Eucerin) after bathing while the skin is still moist to prevent flare-ups. Corticosteroids should be applied to areas of acute exacerbation to reduce and eliminate inflammation.51 Ointments are preferred because they penetrate more efficiently and provide a more effective barrier against moisture loss than creams do. However, they may be less tolerable during the summer months. Low- to intermediate-potency steroids are recommended for the initial management of AD in older children and adolescents. Infants and young children should be treated with one of the lower-potency topical steroids (1% hydrocortisone). High-potency steroids are not usually required for the treatment of eczema except in regions with long-standing lichenified or intractable plaques. Corticosteroids should be applied one to three times daily until the inflammation subsides. The least potent topical steroids should be applied to the face, axilla, and groin because these areas are especially prone to atrophy.1 Pruritus can be treated with antihistamines (hydroxyzine or diphenhydramine). Localized infection should be treated with oral antibiotics effective against *S. aureus* (cephalexin, amoxicillin-clavulanate, or azithromycin).1

**Diaper Dermatitis**

Diaper dermatitis is not one specific entity but incorporates all inflammatory eruptions occurring in the diaper area, including irritant diaper dermatitis and *Candida* diaper dermatitis. Diaper dermatitis has a prevalence of 7% to 35% and a peak incidence at about 6 to 9 months of age. Diaper dermatitis is triggered by the moist, occluded, macerated milieu of the diaper region. Other irritants include friction, diaper detergents, disinfectants, an alkaline pH, and fecal material. Precipitating factors include infrequent diaper changes, insufficient bathing and cleansing, and especially occlusive diapers. The rash typically begins over areas where friction is most pronounced, such as the buttocks, genitals, lower part of the abdomen, and inner aspect of the thighs. It begins as confluent shiny erythema with minimal scale that spares the intertriginous creases. Secondary infection with *Candida albicans* leads to progression of the eruption to a moist, beefy-red patch. Satellite lesions may be appreciated at the periphery. Unlike simple irritant diaper dermatitis, *Candida* diaper dermatitis results in intertriginous involvement. *Candida* has been isolated in up to 80% of children with diaper dermatitis present for more than 3 days. Prevention and treatment of diaper dermatitis are typically achieved with simple measures to decrease irritation in the diaper region. Such measures include frequent diaper changes, the use of highly absorbent diapers, avoidance of cloth diapers, diaper-free periods, and avoidance of plastic or rubber diaper pants. The diaper region should be cleansed gently with mild soap and dried completely. Use of barriers such as zinc oxide, petroleum, or talcum powder may help protect the skin from maceration. Candidal superinfection is treated with topical antifungal cream such as nystatin, clotrimazole, or miconazole.

**Seborrheic Dermatitis (Cradle Cap)**

Seborrheic dermatitis is a chronic inflammatory disease of unknown etiology with a bimodal distribution—infants younger than 6 months and postpubertal adolescents and young adults. It appears as a salmon-colored rash with overlying diffuse greasy yellow or white scales occurring in areas with high sebaceous gland concentration. Lesions are typically located on the scalp but may spread to involve the forehead, nasal folds, eyebrows, and diaper area. The lesions are not typically pruritic or painful. Seborrheic dermatitis can be treated successfully with oatmeal baths and antiseborrheic shampoo (tar shampoo, selenium sulfide). Ketoconazole has been shown to be effective. If the scales are particularly thick or adherent, loosening of the scales with warmed mineral oil and use of a fine-toothed comb before shampooing hasten clearing. If the lesions are especially resistant to these treatments, corticosteroid preparations may be used.

**SEVERE PEDIATRIC RASHES**

**Henoch-Schönlein Purpura**

Henoch-Schönlein purpura (HSP) is a small-vessel vasculitis characterized by a purpuric rash, abdominal pain, arthritis, and hematuria. It is usually seen in children between 3 and 10 years of age. HSP is often preceded by an upper respiratory infection or drug exposure. The pathophysiology of HSP involves deposition of immunoglobulin A, C3, and immune complexes onto small vessels, which leads to systemic inflammation. The HSP classic triad consists of purpura, abdominal pain, and arthritis. The purpura is palpable and most commonly found in a symmetric distribution over the buttocks and extensor surfaces of the legs. The abdominal pain is colicky and may be associated with nausea, vomiting, diarrhea, bloody stools, or intussusception. Hematuria occurs in 10% to 20% of cases, and end-stage renal disease develops in approximately 1% of children. The diagnosis of HSP is made clinically; however, a blood count, coagulation studies, chemistry panel, and urinalysis should be performed to exclude other diagnoses and evaluate renal function. HSP is a self-limited illness and treatment is supportive. Nonsteroidal antiinflammatory drugs (NSAIDs) may be used to reduce pain in the joints and soft tissue. The use of corticosteroids remains controversial. Patients should be hospitalized if complications such as significant bleeding, intussusceptions, or renal failure develop.

**Meningococcemia**

One of the most feared infections in the emergency department is meningococcemia caused by the bacterium *Neisseria meningitidis*. Although meningococcus is relatively rare in the United States, it is uniformly fatal, usually within 24 hours, if untreated. This diagnosis must be considered in any child with fever, headache, and a rash. Meningococcemia may be manifested as a flulike illness with fever, myalgia, vomiting, and arthralgia. In up to two thirds of patients, the early, morbilliform (“measlelike”) rash may mislead the physician into making the diagnosis of a viral exanthem. The disease progresses quickly and exhibits more specific signs: nuchal rigidity, photophobia, altered mental status, and a petechial or purpuric rash. The rash most commonly involves the trunk and lower extremities; however, petechiae may also appear on the face, palms, and mucous membranes. As the infection proceeds, more extensive hemorrhagic lesions are seen on all body areas and progress to large ecchymotic areas. Evaluation of patients with suspected meningitis should include blood cultures, serum chemistries, and a lumbar puncture with cerebrospinal fluid analysis and culture. If meningococcemia is suspected, antibiotics should be administered expeditiously (ceftriaxone or cefotaxime, plus vancomycin). Additional treatments include admission to the intensive care unit (ICU), fluid resuscitation, steroids, vasoppressor agents, and prophylactic treatment of close contacts.

**Staphylococcal Scalded Skin Syndrome**

SSSS is a potentially life-threatening, toxin-mediated disease manifested by tender blistering and widespread desquamation. It usually occurs in children younger than 5 years. The pathophysiology of this illness in children is postulated to be lack of antibodies against the toxin and reduced toxin excretion in comparison with adults. The etiologic agent is exotoxin-producing *S. aureus* of phage group II. The initial staphylococcal infection typically involves the nasopharynx, umbilicus, urinary tract, cutaneous wounds, conjunctiva, or blood. Symptoms of SSSS include a sudden onset of fever and irritability, followed by slight diffuse erythema (resembling a sunburn) and cutaneous tenderness (the infant does not want to be held). The rash initially affects the perioral and perioral-bital regions, neck, axilla, and groin. This is followed by the
crusting exfoliative phase, which occurs around the mouth and eyes. Flaccid bullae also develop. Gentle traction on the affected skin results in epidermal separation (Nikolsky sign), which leaves a shiny, moist, red surface. The mucous membranes are not involved. In newborns, the entire skin surface may be involved (Ritter disease). In SSSS, the cleavage plane for skin sloughing is epidermal. In toxic epidermal necrolysis (TEN), the cleavage plane is at the dermo-epidermal junction. Therefore, in SSSS only the epidermal layer is shed, thus resulting in less morbidity than that occurring with TEN. The diagnosis is made clinically. Complications include sepsis and respiratory distress. Treatment is directed toward elimination of active S. aureus infection to eradicate toxin production. Patients are typically treated with a β-lactamase penicillin or clindamycin. Although antibiotics are recommended, it is unclear whether they measurably alter the course of the disease. Hospitalization for fluid and electrolyte management and for supportive skin care is indicated for most patients.

**Kawasaki Disease**

Kawasaki disease (KD) is an acute, febrile, multisystem illness of unknown etiology that causes widespread vasculitis in young children. The incidence of KD peaks at about 9 to 11 months of age, with 80% of affected children being younger than 5 years. The diagnosis of KD disease can be made if and five of the following criteria are present:

- Temperature higher than 39° C is present for more than 5 days
- Bilateral conjunctival injection: without exudates
- Erythema of the oropharynx or lips: with fissures or strawberry tongue
- Acute cervical lymphadenopathy
- Polymorphous erythematous exanthem: morbilliform, scarlatiniform, or maculopapular (may have plaques or target lesions)
- Edema of the palms and soles: with desquamation occurring 2 to 3 weeks after onset of the illness

Patients with only four of these symptoms meet the criteria if coronary aneurysms are found on echocardiography. The most important clinical complication is coronary artery aneurysms, which may lead to myocardial ischemia and sudden death. Other, less common complications include gallbladder hydrops, diarrhea, obstruction of the small bowel, arthritis, cystitis, pericarditis, myocarditis, valvulitis, and aseptic meningitis. All children with KD should be hospitalized. Management of KD is directed at reducing the risk for coronary artery aneurysm and thrombosis, which is achieved with high-dose aspirin and IVIG.

**Toxic Shock Syndrome**

Staphylococcal TSS is a potentially lethal disease characterized by acute fever, generalized erythroderma, and hypotension. It is due to a localized infection or colonization with a toxin-producing strain of S. aureus. Although TSS is classically associated with menstruating girls using tampons, recent changes in the manufacturing and use of tampons have resulted in a decrease in the incidence of menstrual-associated TSS. Currently, the incidence of nonmenstrual TSS exceeds that of menstrual TSS. Symptoms characteristically begin with high fever, malaise, chills, headache, myalgia, vomiting, and diarrhea. Hypotension and multiorgan involvement follow rapidly. Cutaneous symptoms include a diffuse, blanching, macular eruption beginning on the trunk and spreading to the extremities. This is followed by desquamation, particularly on the palms and soles. The mucous membranes are involved, and erythema and ulceration of the pharyngeal, oral, conjunctival, or vaginal mucosa may occur. Complications include refractory shock, acute renal failure, neurologic symptoms, disseminated intravascular coagulation, acute respiratory distress syndrome, and death. The diagnosis is usually made clinically. However, S. aureus may be isolated from a localized infection. Treatment of TSS includes hemodynamic stabilization of shock and management of multiorgan failure. Importantly, every attempt should be made to identify and treat the infection with local drainage, removal of infective material (tampon), and antistaphylococcal antibiotics.

**TREATMENT**

**CLASSIC EXANTHEMS AND VIRAL RASHES**

The vast majority of these illnesses require only supportive care and surveillance for complications. Treatment of fever and constitutional symptoms with ibuprofen or acetaminophen is helpful. Vitamin A has been shown to reduce risk for mortality and complication in children with measles. Treatment of scarlet fever is with penicillin. Care of patients with varicella should include attention to pruritus, wound care, and prevention of secondary infections. Immunocompromised children with varicella may benefit from acyclovir. Patients with hand-foot-and-mouth disease benefit from soothing preparations (miconazole or clotrimazole) for 2 to 4 weeks. Treatment with penicillin plus clindamycin. Tinea infections of the body, groin, and feet are treated with topical antifungal preparations (miconazole or clotrimazole) for 2 to 4 weeks. Treatment of tinea capitis is with 6 to 8 weeks of oral griseofulvin and selenium sulfide shampoo, with periodic surveillance of liver function tests. Molluscum infections may be left to resolve or, alternatively, treated by cryotherapy, excision, or application of chemicals. Because all these illnesses have the potential for serious complications, close monitoring for these adverse events is required.

**SKIN AND SOFT TISSUE INFECTIONS**

The mainstay of treatment of impetigo is antibiotic therapy directed against Staphylococcus and Streptococcus. Agents include cephalaxin, amoxicillin-clavulanate, azithromycin, dicloxacillin, and oxacillin. Treatment of bacterial reservoirs with mupirocin may also be required. Erysipelas requires treatment with penicillin plus clindamycin. Tinea infections of the body, groin, and feet are treated with topical antifungal preparations (miconazole or clotrimazole) for 2 to 4 weeks. Tinea capitis is treated with 6 to 8 weeks of oral griseofulvin and selenium sulfide shampoo, with periodic surveillance of liver function tests. Molluscum infections may be left to resolve or, alternatively, treated by cryotherapy, excision, or application of chemicals. Because all these illnesses have the potential for serious complications, close monitoring for these adverse events is required.

**PEDIATRIC DERMATITIS**

Treatment of atopic dermatitis is multidisciplinary in approach and includes behavior modification, emollients, topical steroids, and antihistamines. Diaper dermatitis is managed with measures aimed at decreasing regional irritation, including changes in diapering routine, use of barriers, and monitoring...
for candidal superinfection. Seborrheic dermatitis is treated with oatmeal baths and antiseborrheic shampoos. Ketoconazole is also effective.

**SEVERE PEDIATRIC RASHES**

HSP is usually a self-limited disease, and treatment is supportive. Relief of pain symptoms with NSAIDs is helpful. Meningococcemia is an overwhelming bacterial infection that requires ICU admission, early antibiotic therapy, fluid resuscitation, vasopressor support, and prophylaxis of close contacts. SSSS is also potentially life-threatening and mandates hospital admission, early antibiotic therapy, fluid and electrolyte management, and supportive skin care. All children with KD also require admission. Treatment with high-dose aspirin and IVIG is required, as well as surveillance for cardiovascular complications. Treatment of TSS entails ICU admission, hemodynamic stabilization, removal of infective source material, and early antibiotic therapy. All these illnesses have potentially devastating complications, and close and continual monitoring is therefore mandatory.

**FOLLOW-UP AND PATIENT EDUCATION**

**CLASSIC EXANTHEMS AND VIRAL RASHES**
The majority of these illnesses are self-limited or treated with simple measures. Appropriate follow-up for patients with these classic exanthems and viral rashes is with their pediatrician. The physician is a valuable resource for patient education, parent reassurance, and close monitoring of complications.

**SKIN AND SOFT TISSUE INFECTIONS**
These illnesses are usually the result of common bacterial, fungal, or viral infections and should be monitored closely by the patient’s pediatrician to ensure complete resolution, as well as provide family education regarding transmission and eradication of carrier states and identify any complications that may develop.

**DERMATITIS**
These entities are common in most families and easily managed in concert with the patient’s pediatrician. AD may benefit from dermatologic referral. All these conditions require serial evaluation for appropriate resolution and surveillance for complications.

Pediatric Cardiac Disorders

Nathan W. Mick

KEY POINTS

- Congenital heart disease is typically diagnosed in utero or before discharge from the newborn nursery, but delayed manifestations usually occur within the first 2 weeks of life when the ductus arteriosus closes.
- Congenital heart disease should be considered in a neonate who is in shock or has congestive heart failure or cyanosis.
- Subtle signs of cardiac disease in children include sweating, irritability, and poor feeding.
- Echocardiography is used for the diagnosis of structural congenital heart disease.
- Prostaglandin E\textsubscript{1} can be lifesaving in cases of ductal-dependent congenital heart disease.

EPIDEMIOLOGY

The spectrum of congenital pediatric cardiac disorders includes structural congenital heart disease (CHD) and rhythm disturbances such as supraventricular tachycardia (SVT), long QTc syndrome, and congenital complete heart block.

Structural CHD occurs in approximately 8 in 1000 live births. Most congenital lesions are diagnosed in utero or in the newborn nursery, but a significant proportion may not be manifested until 1 to 2 weeks of life, when the ductus arteriosus closes. In fact, a significant proportion of cases of CHD are diagnosed after hospital discharge. Normal findings on newborn evaluation does not rule out potentially significant lesions, and a high index of suspicion is critical to ensure timely diagnosis.

Many risk factors for the development of CHD have been identified (Box 19.1), including a family history of CHD, maternal diabetes (associated with ventricular septal defect [VSD], hypertrophic cardiomyopathy, and transposition of the great arteries [TGA]), and fetal drug exposure (e.g., Ebstein anomaly with maternal lithium therapy). Pediatric cardiac disease may be challenging because it may mimic more common illnesses, such as sepsis.

Rhythm disturbances are also important causes of pediatric cardiac disease and can occur in children with structural heart disease or in those with structurally normal hearts. SVT is the most common pediatric cardiac arrhythmia and includes atrioventricular nodal reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT), and preexcitation conditions such as Wolf-Parkinson-White syndrome. Congenital complete heart block is associated with maternal connective tissue disease and the presence of anti-Ro/SSA and anti–La-SSB antibodies. Long QTc syndrome may be congenital or acquired; the congenital form is estimated to occur in 1 in 7000 to 10,000 live births. Congenital long QTc syndrome may occur in an autosomal dominant form (Romano-Ward syndrome) or in an autosomal recessive form (Jervell and Lange-Nielsen syndrome) associated with sensorineural hearing loss.

PATHOPHYSIOLOGY

Fetal circulatory anatomy is designed to transport oxygenated blood from the placenta to the systemic circulation while bypassing the lungs (Fig. 19.1). Fetal oxygenation occurs at the placenta, and blood is returned to the right atrium through the ductus venosus after bypassing the liver. Most of the oxygen-rich blood is shunted across the foramen ovale into the left atrium and is then delivered to the systemic circulation via the aorta. Some flow travels from the right atrium into the right ventricle and enters the pulmonary arteries. The pulmonary vasculature is constricted, and flow is shunted through the ductus arteriosus and mixes with blood in the aorta to supply the systemic circulation.

Birth results in a complex series of changes induced by expansion and oxygenation of the lungs. Oxygenation of the lungs leads to a marked decrease in pulmonary vascular resistance and a subsequent increase in pulmonary blood flow. Increasing pulmonary blood flow results in greater return of blood to the left atrium, which functionally closes the foramen ovale (the foramen may remain “probe patent” into adulthood). The decrease in pulmonary vascular resistance is coupled with an increase in systemic vascular resistance, and ductal flow reverses to become left to right. The blood traversing the ductus arteriosus is now highly oxygenated, a change that typically stimulates closure by 48 hours of life. In certain cases, the ductus arteriosus does not close until 1 to 2 weeks of life, and so-called ductal-dependent cardiac lesions may be manifested at this time (Box 19.2). The increased pressure and volume demands on the left ventricle stimulate growth of the left ventricle, and the decreased load on the right ventricle...
Normal fetal circulatory anatomy.

Fig. 19.1 Normal fetal circulatory anatomy. Ao, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

BOX 19.1 Risk Factors for the Development of Congenital Heart Disease

Risk for congenital heart disease is increased with one affected parent or sibling and is three times greater if two close relatives have such disease.
Maternal diabetes is associated with hypertrophic cardiomyopathy, ventricular septal defect, and transposition of the great arteries.
Maternal phenytoin use is associated with aortic stenosis and pulmonic stenosis.
Maternal lithium use is associated with Ebstein anomaly.
Fetal alcohol syndrome is associated with atrial septal defect and ventricular septal defect.

BOX 19.2 Congenital Heart Lesions That Depend on Patency of the Ductus Arteriosus

Right-to-Left Shunting Critical for Relief of Left-Sided Obstruction (Typically Present with Shock)

- Hypoplastic left heart syndrome
- Total anomalous pulmonary venous return with obstruction
- Critical coarctation of the aorta
- Interrupted aortic arch
- Congenital aortic stenosis

Left-to-Right Shunting Critical for Relief of Right-Sided Obstruction (Typically Present with Cyanosis)

- Tetralogy of Fallot with severe right outflow tract obstruction
- Tricuspid atresia
- Pulmonic atresia
- Ebstein anomaly

from decreased pulmonary vascular resistance results in a reduction in right ventricular mass.

PRESENTING SIGNS AND SYMPTOMS

Infants with previously undiagnosed structural CHD are typically initially seen in the emergency department (ED) with shock, congestive heart failure (CHF), cyanosis, or a combination of these symptoms. Left-sided obstructive lesions such as hypoplastic left heart syndrome and coarctation of the aorta are manifested as shock as the ductus arteriosus closes and the blood supply to the systemic circulation dwindles. Shock can also be the initial sign of total anomalous pulmonary venous return (TAPVR) with obstruction. Evidence of poor perfusion, such as lethargy, mottled extremities, tachycardia, and tachypnea, is typically present.
Sepsis and other noncardiac conditions (e.g., salt-wasting crisis in congenital adrenal hyperplasia) can cause similar findings. Shock may also be the manifestation of SVT or complete heart block that has become decompensated (Box 19.3).

CHF is a common manifestation of both structural heart disease and congenital rhythm disturbances. Although respiratory distress, tachypnea, and rales may be present, subtler signs such as poor feeding and hepatomegaly may be the only manifestations of CHF. Assessment of the liver’s edge is a critical portion of the physical examination in these infants. Peripheral edema as a manifestation of CHF is rare in infants. Acyanotic heart diseases with large left-to-right shunts, such as congenital aortic stenosis, interrupted aortic arch, and coarctation of the aorta, are manifested as CHF because blood preferentially flows into the low-resistance pulmonary bed (Box 19.3). TAPVR and VSD can also be manifested as CHF as a result of volume overload of the right ventricle. Rhythm abnormalities such as sustained SVT and congenital complete heart block can likewise be manifested as CHF as a result of poor forward flow.

Cyanosis can be the first manifestation of CHD in infants, and severe lesions are typically diagnosed in utero or in the newborn nursery. Some lesions may escape detection, however, and first be recognized later in the neonatal period. Central...
cyanosis affecting the lips, mucous membranes, and trunk is due to decreased arterial oxygen saturation and is always pathologic. The differential diagnosis of central cyanosis is presented in Table 19.2. Peripheral cyanosis limited to the extremities or circumoral region is a normal newborn finding but can also be due to non-CHD causes such as sepsis, exposure to cold, and poor cardiac output.

**Differential Diagnosis and Medical Decision Making**

**Lesion-Specific Presentations**

**Lesions Manifested as Decreased Pulmonary Blood Flow**

**Tetralogy of Fallot**

The tetralogy of Fallot, the most common structural CHD occurring outside the neonatal period, consists of the following anatomic abnormalities: a
large VSD, varying degrees of right ventricular outflow tract obstruction, an overriding aorta, and right ventricular hypertrophy. Time of appearance is linked to the severity of right ventricular outflow tract obstruction and thus to the amount of pulmonary blood flow, with severe obstruction causing cyanosis in the newborn and earlier age of occurrence. Less severe obstruction (a “pink” tetralogy) may delay diagnosis, or an infant may be taken to the ED with “tet spells” in which the child becomes episodically more cyanotic as a result of worsening of the right ventricular outflow tract obstruction and decreased pulmonary blood flow.

Physical findings consist of right ventricular heave and a single second heart sound (no pulmonic valve component). A harsh systolic ejection murmur, a finding reflecting right ventricular outflow tract obstruction, may be present. The murmur characteristically softens as the severity of obstruction worsens and more blood is shunted across the VSD.

TRICUSPID ATRESIA Tricuspid atresia is characterized by complete absence of the tricuspid valve, a hypoplastic right ventricle, and the presence of a VSD. The size of the VSD determines the amount of pulmonary blood flow. Large VSDs may allow relatively normal pulmonary blood flow and delay detection. In these cases, because the left ventricle is the only functioning pumping chamber, fluid overload may occur, and affected infants and children may have heart failure and hepato-megaly. Infants with small VSDs are dependent on the ductus arteriosus for pulmonary blood flow and are seen in the neonatal period with cyanosis as the ductus arteriosus closes. Blood returning to the heart enters the right atrium and flows across the foramen ovale (which remains patent) to enter the systemic circulation. A murmur of pulmonic stenosis may be present if flow across the pulmonary valve is sufficient to be detected on auscultation.

PULMONARY ATRESIA Pulmonary atresia with an intact ventricular septum is associated with a hypoplastic right ventricle and is dependent on an atrial septal defect (ASD) and right-to-left shunting. Pulmonary blood flow depends on the ductus arteriosus, so affected patients are seen in the neonatal period with cyanosis as the ductus arteriosus closes. Physical examination typically demonstrates a single second heart sound (no pulmonic component), and if a murmur is present, it is typical of tricuspid regurgitation.

Lesions Manifested as Increased Pulmonary Blood Flow

TOTAL ANOMALOUS PULMONARY VENOUS RETURN TAPVR occurs as a result of embryologic failure of the pulmonary veins to form a connection to the left atrium. The pulmonary veins can dump into the superior vena cava (supracardiac connection), into the portal vein (infracardiac connection), or into the right atrium via the coronary sinus. Obstruction of any of these anomalous connections leads to pulmonary congestion, respiratory distress, and varying levels of heart failure. Cyanosis may develop because of the decrease in oxygenated blood returning to the heart. Physical findings may indicate heart failure, and TAPVR with obstruction is characterized by a fixed, widely split second heart sound.

TRUNCUS ARTERIOSUS Truncus arteriosus is defined as the presence of a single trunk arising from the heart that functions as both the aorta and the pulmonary artery. A single semilunar valve is present and overrides a VSD, thereby allowing complete mixing of systemic and pulmonary blood. As pulmonary vascular resistance falls after birth, more and more blood travels into the low-resistance pulmonary circuit, and heart failure develops. In affected infants in whom truncus arteriosus was not diagnosed in the newborn nursery, it is typically diagnosed when heart failure develops. Physical findings include a wide pulse pressure and a systolic ejection murmur representing increased flow across the semilunar valve. A single second heart sound may also be found.

TRANSPOSITION OF THE GREAT ARTERIES TGA is a common congenital defect in which the pulmonary and systemic circuits are arranged in parallel rather than in series. TGA may be associated with a VSD or ASD, but more commonly, no other defect is present, and mixing of oxygenated and deoxygenated blood occurs only at the ductus arteriosus. Infants with TGA are cyanotic at birth because of right-to-left shunting, and the cyanosis gets worse as the ductus arteriosus closes. If therapy to keep the ductus arteriosus open (see later) is not instituted promptly, hypoxemia, acidosis, and death quickly ensue. In TGA without an associated VSD or ASD, there may be no other telltale signs on physical examination. Children with TGA and an associated VSD or ASD may be seen later in the newborn period with heart failure, and a VSD murmur may be heard.

HYPOPLASTIC LEFT HEART SYNDROME Hypoplastic left heart syndrome involves a severely hypoplastic left ventricle and small, atretic mitral and aortic valves. The right ventricle is the default pumping chamber to both the lungs and the systemic circulation, and all systemic circulation crosses from the pulmonary artery through the ductus arteriosus to supply the body. Cyanosis from birth is the rule, and the lesions are typically diagnosed in utero or in the nursery. As the ductus arteriosus closes, all blood returning to the heart goes to the lungs, and heart failure develops as a result of volume overload. The pathway to the systemic circulation is also compromised, and shock develops. Physical findings include tricuspid and pulmonic murmurs because of increased flow. Hepatomegaly may be apparent as failure develops.

ACYANOTIC STRUCTURAL CONGENITAL HEART DISEASE

Coarctation of the Aorta Coarctation of the aorta refers to congenital narrowing of the aorta, most commonly at the level of the ductus arteriosus. Infants with coarctation have a normal oxygen saturation value and typically no cyanosis. When the ductus arteriosus is open, blood is able to bypass the obstruction, and few symptoms are present. As the ductus arteriosus closes, the systemic circulation may be compromised by the narrowed aorta. “Critical” coarctation occurs when the narrowing is severe, and these infants are brought to the ED when the ductus arteriosus closes and signs of shock appear. If the narrowing is less severe, the coarctation may be diagnosed later in life. Physical findings consistent with coarctation include normal or increased blood pressure in the upper extremities and decreased perfusion to the lower extremities. Four-extremity blood pressure should be measured in any child in whom the diagnosis of coarctation of the aorta is being
Congenital Aortic Stenosis
Congenital aortic stenosis typically results when an aortic valve is congenitally bicuspid rather than tricuspid. Most infants with aortic stenosis are asymptomatic, and problems do not develop until later in life. The condition may be diagnosed in affected children as part of an evaluation for a heart murmur. If the stenosis is severe, symptoms may develop in infancy. Typically, critical congenital aortic stenosis becomes apparent as the ductus arteriosus closes, and the findings consist of heart failure as a result of increased pulmonary blood flow and signs of systemic hypoperfusion. A murmur may not be appreciable because of poor cardiac output. Physical findings include signs of shock with poor peripheral perfusion.

CONGENITAL RHYTHM DISTURBANCES

Supraventricular Tachycardia
SVT is characterized by a narrow-complex elevated heart rhythm that is regular and generally above 220 beats/min. AVRT, including Wolff-Parkinson-White syndrome, and AVNRT are the two most frequent forms of SVT in children. AVRT is more common in infants and younger children, with AVNRT rising in frequency after 2 years of age. The majority of children with SVT have structurally normal hearts, although SVT is associated with CHD in about 25% of cases. Infants may exhibit respiratory distress, poor feeding, and irritability, and the rhythm abnormality may not be recognized until heart failure develops. Older children may have syncope, chest pain, palpitations, or lightheadedness. Sudden cardiac death is rare with SVT unless an underlying structural heart disease is present. Physical findings include tachycardia, hypotension, and signs of heart failure.

Long QTc Syndrome
Many patients with long QTc syndrome are asymptomatic, although syncope, palpitations, lightheadedness, or cardiac arrest may bring affected children to medical attention. Among those who have symptoms, a significant proportion have exercise-related complaints. Long QTc syndrome may actually cause some cases of sudden infant death syndrome. A family history of sudden cardiac death may be elicited. Autosomal recessive forms of congenital long QTc syndrome are associated with sensorineural hearing loss. Anderson syndrome is a rare autosomal dominant form of long QTc syndrome associated with hypokalemic periodic paralysis, facial dysmorphisms, and cardiac arrhythmias. Torsades de pointes is the classic rhythm abnormality occurring in long QTc syndrome, and the baseline ECG findings may consist of bradycardia or atrioventricular block. Physical examination may demonstrate signs of associated syndromic abnormalities.

Congenital Complete Heart Block
Congenital complete heart block may be manifested at any time during childhood, although many cases are diagnosed in utero. The common finding is bradycardia. In infants in whom congenital complete heart block is diagnosed after birth, physical findings include cannon waves in the neck (as a result of atrial contraction against closed tricuspid valves) and signs of poor perfusion. A maternal history of connective tissue disease, particularly systemic lupus erythematosus, is sometimes present. Congenital complete heart block in older patients may be manifested as syncope or sudden cardiac death.

DIAGNOSTIC TESTING

Evaluation of an infant in critical condition with suspected cardiac disease should focus on excluding noncardiac causes of the patient’s symptoms while attempting to confirm a cardiac lesion. The distinction between sepsis and decompensated cardiac disease is often difficult, and it is advisable to rule out sepsis in critically ill children and begin treatment with empirically chosen antibiotics. In children with cardiac disease, polycythemia from chronic hypoxia may be noted. A thorough physical examination is critical to evaluate for sources of possible infection (indicating possible sepsis) or ambiguous genitalia (seen with salt-wasting crisis secondary to congenital adrenal hyperplasia).

ELECTROCARDIOGRAM
A 12-lead ECG study should be performed on every infant and child in whom heart disease is suspected. If structural CHD is part of the differential diagnosis, a 15-lead ECG study (including leads V3R, V4R, and V7) may give added information. Correct interpretation of pediatric ECG values can be challenging because most normal adult values are abnormal in the newborn period. Normal ECG parameters in children are presented in Table 19.4, whereas Tables 19.5 and 19.6 list ECG findings associated with specific cardiac lesions. SVT is typically manifested as a narrow-complex tachycardia with a regular rhythm. Heart rates are generally higher than 220 beats/min, and P waves may be visible. SVT with aberrant conduction (manifested as a wide-complex tachycardia) is rare in the pediatric population, and a wide-complex tachycardia should be considered ventricular in origin until proved otherwise. Long QTc syndrome is characterized by a QTc interval that is prolonged (>440 msec). Acquired causes of a prolonged QTc, such as electrolyte abnormality (hypocalcemia, hypokalemia, hypomagnesemia) and drug effect (erythromycin, trimethoprim, and others), should be ruled out.

CHEST RADIOGRAPH
A chest radiograph is useful in the evaluation of suspected cardiac disease because it allows assessment of heart size, pulmonary vascular markings, and situs of the aortic arch. Heart size can help differentiate between a cardiac lesion and sepsis. An enlarged heart may be seen with left-sided obstructive lesions such as congenital aortic stenosis, interrupted aortic arch, and critical coarctation of the aorta. Certain CHD lesions have specific radiographic findings, such as the egg-on-a-string pattern seen with TGA and the boat-shaped heart with the tetralogy of Fallot (Fig. 19.2). Structural CHD can be broken down into lesions that cause an increase in pulmonary blood flow and lesions that cause decreased pulmonary blood flow; the presence of increased pulmonary vascular markings on a radiograph can aid in diagnosis (Box 19.4). The aorta is normally left sided, and a right-sided aortic arch can be seen with the tetralogy of Fallot, TGA, and truncus arteriosus.
HYPEROXIA TEST
Useful in distinguishing cardiac from pulmonary sources of cyanosis, the hyperoxia test hinges on the premise that supplemental oxygen does not increase PaO₂ in the presence of an intracardiac shunt to the same degree that it does with isolated pulmonary disease (see the Tips and Tricks box). A child with TGA or severe right ventricular outflow tract obstruction (i.e., tetralogy of Fallot, pulmonary atresia, tricuspid atresia) typically has PaO₂ values of less than 60 mm Hg during hyperoxia. In lesions such as truncus arteriosus, TAPVR, and hypoplastic left heart syndrome, which involve intracardiac mixing, PaO₂ values range between 75 and 150 mm Hg. It is critical to

**BOX 19.4 Lesion-Specific Manifestations Based on Pulmonary Blood Flow**

**Congenital Lesions Causing Increased Pulmonary Blood Flow or Left-to-Right Shunting**
- Total anomalous pulmonary venous return
- Tricuspid atresia
- Transposition of the great arteries
- Truncus arteriosus
- Hypoplastic left heart syndrome
- Isolated atrial septal defect
- Isolated ventricular septal defect

**Congenital Lesions Causing Decreased Pulmonary Blood Flow or Right-to-Left Shunting**
- Tetralogy of Fallot
- Tricuspid atresia
- Pulmonary atresia

**ECHOCARDIOGRAPHY**

Echocardiography is the definitive test for suspected structural heart disease. Any infant with central cyanosis, cardiac enlargement on chest radiography, a suspicious murmur, or a pulse differential across the ductus arteriosus or whose Pa$_{O_2}$ fails to rise with the hyperoxia test should be evaluated with echocardiography. This modality also allows evaluation of heart function and pericardial fluid in those with acquired conditions such as myocarditis. Echocardiography should likewise be considered in the evaluation for suspected SVT because a significant proportion of cases are associated with structural CHD.

**The Hyperoxia Test**

Have the patient breathe 100% oxygen for 10 minutes (hyperoxia), and then draw a postductal blood sample for arterial blood gas analysis. Pulmonary disease is suggested if Pa$_{O_2}$ with 100% oxygen is greater than 150 mm Hg. If the Pa$_{O_2}$ value is below 150 mm Hg during hyperoxia, a cyanotic cardiac lesion should be suspected.

**TIPS AND TRICKS**

**Fig. 19.2 Classic chest radiographic findings in children with congenital heart disease.**

*A* Tetralogy of Fallot (boot-shaped heart).

TREATMENT

INTERVENTIONS

Initial management of an infant or child with suspected cardiac disease who appears in extremis should focus on cardiopulmonary support, establishment of intravenous (IV) access, and appropriate monitoring. Intubation may be required, and rapid-sequence intubation should be considered the method of choice for management of the pediatric airway. Because the signs and symptoms of decompensated pediatric cardiac disease and sepsis are similar, empirical treatment with broad-spectrum antibiotics (ampicillin, 100 to 200 mg/kg/day, and gentamicin, 5 to 10 mg/kg/day, or ceftriaxone, 100 mg/kg if the child is older than 28 days) should be started after appropriate specimens for blood, urine, and cerebrospinal fluid culture are obtained. If the shock does not respond to fluid resuscitation (normal saline, 20 mL/kg intravenously to a total of 60 mL/kg), inotropes such as dopamine (start with 5 mcg/kg/min and titrate to effect) or dobutamine (0.5 mcg/kg/min) may be added.

If a neonate is in shock and does not promptly improve with IV fluid administration, CHD may be present; a neonatologist should be called and prostaglandin E1 treatment should be considered, even presumptively. Prostaglandin E1, infusion can be lifesaving in infants with ductal-dependent pulmonary or systemic blood flow. The infusion should be started at 0.1 mcg/kg/min and increased or decreased according to clinical response. Side effects include flushing, diarrhea, fever, and apnea. Many such patients require intubation, especially those being transferred to another hospital.

TET SPELLS

Hypercyanotic tet spells typically occur in infants with uncorrected tetralogy of Fallot and should be treated with supplemental oxygen, morphine (0.1 mg/kg), and knee-chest positioning. Bicarbonate administered as a 1-mEq/kg bolus should also be considered to relieve the acidosis common in tet spells. If these measures fail, in consultation with a pediatric cardiologist consideration can be given to phenylephrine infusion (0.1 mcg/kg/min titrated to effect) to increase systemic vascular resistance and drive more blood flow across the right ventricular outflow tract obstruction.

SUPRAVENTRICULAR TACHYCARDIA

Treatment of SVT depends on the clinical stability of the child. If signs of decompensation (hypotension, poor perfusion) are present, immediate synchronized cardioversion at 0.5 to 1 J/kg should be performed. In a more stable child, vagal maneuvers (i.e., application of ice to the face, Valsalva maneuver) may be attempted. Once IV access is obtained, adenosine (0.1 mg/kg to a maximum dose of 6 mg) should be administered via rapid IV bolus if vagal maneuvers fail. If no response is seen after the first dose, the second dose should be 0.2 mg/kg to a maximum of 12 mg, administered in the same manner.

LONG QTc SYNDROME

The mainstay of therapy in patients in whom congenital long QTc syndrome is diagnosed is beta-blocker therapy, which should be given in consultation with a pediatric cardiologist (Box 19.5). Treatment of torsades de pointes associated with long QTc syndrome should consist of cardioversion (0.5 to 1 J/kg) if the patient is unstable. Magnesium sulfate (25 to 50 mg/kg intravenously) is the antiarrhythmic agent of choice for the treatment of torsades.

NEXT STEPS IN CARE: ADMISSION AND DISCHARGE

Any child in extremis with a new diagnosis of CHD should be admitted to an intensive care unit in a hospital with pediatric cardiology services until stabilized. Children who are less ill may be managed on an appropriately monitored floor. Outpatient management may be appropriate for children in whom structural heart disease is suspected on the basis of a murmur but who have no other symptoms.

Patients with SVT who are asymptomatic, who have no signs of heart failure, and in whom the SVT converted to a normal sinus rhythm in the ED can be considered for outpatient management if appropriate follow-up with a pediatric cardiologist can be arranged. Patients with symptomatic long QTc syndrome (resuscitated arrest, torsades de pointes) should be admitted to a monitored bed. Most other cases can be managed with outpatient pediatric cardiology follow-up. A child with congenital complete heart block, when diagnosed, should be admitted to a monitored setting because of the risk for hemodynamic compromise.

DEVELOPMENTAL ANATOMY OF THE KIDNEYS

The full complement of nephrons is present at birth, although newborn nephrons are heterogeneous in glomerular size and proximal tubule length. Anatomy and function mature postnatally. Although fetal urine is excreted into the bladder by 10 to 11 weeks of gestation, the ability to conserve and excrete sodium, concentrate urine, and reabsorb substrates such as glucose evolves to maturity over the first 2 years of life. In utero, the glomerular filtration rate (GFR) is minimal secondarily to placental function; at birth, the GFR is 10% of adult values and matures by 12 to 24 months of age. Therefore, an increase in an infant’s creatinine to “normal” adult ranges can indicate pathology.

KEY POINTS

Children often cannot differentiate between abdominal pain and groin pain—a complete physical examination is therefore necessary.

The pathophysiology, clinical findings, and treatment of paraphimosis, testicular torsion, and priapism are similar in both the pediatric and adult population. They are emergencies that require immediate intervention.

The most common cause of acute renal failure in children is hemolytic-uremic syndrome.

Poststreptococcal glomerulonephritis is the most common cause of acute glomerulonephritis. IgA nephropathy is the most commonly diagnosed cause of glomerulonephritis in adolescents.

One third of patients with Henoch-Schönlein purpura have renal involvement. This disorder is the most common form of vasculitis in childhood and is usually characterized by the triad of abdominal pain, arthritis, and purpura.

DEVELOPMENTAL BASIS OF GENITOURINARY TRACT PATHOLOGY

The male genital organs originate within the abdominal cavity and then migrate externally during fetal development. Delays in testicular migration explain much of the pathology of scrotal masses. The testes, attached to their blood supply, drag their peritoneal covering (known as the tunica vaginalis) through the inguinal canal and into the scrotal sac. The left testicle usually completes migration before the right testicle, thus explaining the increased frequency of right-sided inguinal hernias and undescended right testicles. Impediments to migration cause cryptorchidism. Failure of the peritoneal space to close after testicular migration can lead to hydroceles and inguinal hernias. Failure of fixation of the testes within the scrotal sac allows testicular torsion to occur. Differences in venous return make left-sided varicoceles much more common than right-sided ones.

Posterior urethral valves represent a disturbance in urethral development in males that is the leading cause of lower urinary tract obstruction in neonates. One third of patients with posterior urethral valves progress to end-stage renal disease, and 10% to 15% of children who require renal transplantation have posterior urethral valves.

CRYPTORCHIDISM (UNDESCENDED TESTIS)

By birth, the testes have usually descended from the abdominal cavity into the scrotum; only 3% to 5% of full-term newborns have an undescended testicle. Although spontaneous descent does occur in the first year of life, 0.8% of males are still affected at 12 months of age, and spontaneous descent becomes increasingly unlikely after 6 months. With a careful physical examination, 80% of undescended testes are palpable, most commonly in the inguinal canal. Children with undescended testes are at higher risk for torsion, trauma, and malignancy.

CLINICAL PRESENTATION AND DIAGNOSIS

Children with undescended testes are ideally identified by careful physical examination before any complications occur. The differential diagnosis of testes that are not palpable includes undescended, retractile, and absent testes. Children younger than 1 year should be examined while they are relaxed in a warm bath because the testes can be retracted during
A varicocele is a collection of spermatic venous varicosities in the scrotum caused by incomplete drainage of the pampiniform plexus (Fig. 20.2). They are rare in children younger than 10 years. Varicoceles most commonly develop between 10 and 15 years of age and have an incidence of approximately 15% in males. The majority (85% to 95%) of varicoceles are left sided, the result of spermatic venous incompetence secondary to drainage of the left spermatic vein into the renal vein at a right angle.

IVC, Inferior vena cava; STD, sexually transmitted disease.
*Emergency condition.

CLINICAL PRESENTATION AND DIAGNOSIS

Right-sided varicoceles should prompt an evaluation for intraabdominal pathology such as thrombosis or a tumor causing compression of the inferior vena cava. Similarly, sudden onset of a left-sided varicocele should raise suspicion for renal cell carcinoma with obstruction of the left renal vein. The differential diagnosis of varicoceles and other scrotal masses is outlined in Table 20.1.

Varicoceles can cause mild discomfort and may lead to infertility in adult males. They are usually diagnosed on routine physical examination and are characterized by a full hemiscrotum without skin changes and a classic “bag of worms” finding on palpation.

TREATMENT

A varicocele is generally an incidental finding in adolescence and is not an emergency. Referral to outpatient urology is appropriate.

TESTICULAR TORSION

The pathophysiology, clinical findings, and treatment of testicular torsion in the pediatric population is similar to that in adults. Detailed discussion of torsion can be found in Chapter 111.

INGUINAL Hernia

An inguinal hernia occurs when an intraabdominal organ, usually intestine, herniates into a patent processus vaginalis (see Fig. 20.1). An incarcerated hernia refers to an intestinal loop that is not reducible. A strangulated hernia results when the blood supply to the intestinal loop is obstructed and bowel ischemia ensues.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Inguinal hernias occur in 15 of every 1000 live births. The incidence in premature and low-birth-weight infants is much higher (approximately 30%), whereas the incidence in males is three to four times higher than that in females. They are most commonly identified during the first year of life, with a peak in diagnosis during the first month. Indirect hernias are more common on the right side (60%) because of later testicular descent into the scrotum. If a left-sided hernia exists, there is a strong possibility that an occult right-sided hernia is present. A family history of hernia, prematurity, or undescended testicle is associated with inguinal hernias.
Incarnation is more common with small hernias and occurs frequently during the first 6 months of life, less commonly after 2 years of age, and rarely after the age of 5. Strangulation and perforation can occur within 2 hours of decreased blood flow. Incarceration occurs more frequently in females; however, it is the ovaries, not the intestines, that herniate and become incarcerated.

**TREATMENT**

Given the high frequency of incarceration in the first year of life, hernias found on routine examination without symptoms should be referred for surgical repair. Approximately 90% of complications can be avoided if surgery is performed within the first month after diagnosis.

**IDIOPATHIC SCROTAL EDEMA**

Idiopathic scrotal edema is manifested as painless erythema and induration of the scrotum. More than 75% of cases occur in boys younger than 10 years. Two thirds of cases are unilateral.

**CLINICAL PRESENTATION**

Patients may complain of pruritus. Edema and erythema may extend to the phallus, groin, and abdomen. The testes and epididymis will have no palpable masses, and systemic symptoms are rare.

**TREATMENT AND DISPOSITION**

Idiopathic scrotal edema is a diagnosis of exclusion. If acute pathology has been excluded, patients can be discharged home with outpatient follow-up. Most cases resolve spontaneously within a few days and do not require specific treatment. The recurrence rate is 21%.

**CARCINOMA**

Testicular and scrotal cancer accounts for 1% of solid tumors in children. The incidence is increased in patients with bilateral cryptorchidism.

**CLINICAL PRESENTATION AND DIAGNOSIS**

On examination, a painless unilateral mass can be palpated separately from the testis; there may also be a sensation of fullness, tugging, or increased weight in the scrotum associated with testicular enlargement. A reactive hydrocele is present in 7% to 25% of patients and may lead to a delay in diagnosis. Further examination reveals a firm mass, either smooth or nodular, that does not transilluminate. Lymphadenopathy, petechiae, abdominal masses, hepatosplenomegaly, or gynecomastia may be present. Lymphoma and leukemia can metastasize to the testicles and be manifested similarly.

A complete blood count, urinalysis, urine test for human chorionic gonadotropin (produced by germ cell tumors), and testicular ultrasound images should be obtained.

**TREATMENT**

Management consists of prompt urologic and oncologic consultation for biopsy and staging.

**PHIMOSIS**

Phimosis is a constriction of the penile foreskin that results in an inability to retract the prepuce over the glans. A fully retractable foreskin is present in 4% of newborns, 50% of 1-year-olds, 80% of 2-year-olds, and 90% of 4-year-olds. In the remaining cases, the foreskin may not be retractable until puberty.

**CLINICAL PRESENTATION**

Although most cases of phimosis in children are physiologic, symptoms may include pain, hematuria, and in severe cases, urinary obstruction. Adolescents may complain of pain on erection secondary to tension on the foreskin from glandular adhesions. Phimosis can also result from trauma, infection, chemical irritation, and poor hygiene or as a complication of circumcision. Severe stenosis or obstructive uropathy can result from chronic symptomatic phimosis.

**TREATMENT**

Because the ability to retract the foreskin is age related, parents should not forcefully retract the prepuce. Good hygiene should be taught. If the child has signs of urinary outlet obstruction, dilation of the meatus by gentle use of forceps is warranted.

Steroid preparations (0.05% to 5% betamethasone cream two to four times daily or 1% hydrocortisone cream two to three times daily) have been used with varying success. Severe phimosis may mandate incision of the dorsal inner foreskin by a urologist.

**PARAPHIMOSIS**

Paraphimosis is a urologic emergency in which the foreskin of an uncircumcised male is retracted behind the glans penis and acts as a constricting band (Fig. 20.3). The resulting venous and lymphatic congestion precludes returning the foreskin to its normal position, threatens arterial blood flow to the glans penis, and can result in penile necrosis, gangrene, or infarction of the glans over a period of hours to days. In infants and young boys, paraphimosis most commonly results after cleaning by a caretaker.
CHAPTER 20  PEDIATRIC GENITOURINARY AND RENAL DISORDERS

CLINICAL PRESENTATION AND DIAGNOSIS

Balanitis and balanoposthitis can be caused by trauma; by irritation such as contact dermatitis from urine, soaps, powders, and ointments; or by infection. Causative agents of infectious balanoposthitis include group A streptococci (GAS), anaerobic bacteria, Candida, and sexually transmitted infections such as gonorrhea and chlamydial infection. Most children with GAS balanoposthitis have a characteristic moist balanoposthitis caused by a nonretractable prepuce, often in conjunction with a current or recent GAS infection at another site.7 Signs of group A β-hemolytic streptococcal infection include pain, intense fiery redness, and a moist, glistening transudate or exudate under the prepuce. Streptococcal infection can be diagnosed by rapid antigen detection and culture.

Gonorrhea and chlamydial infection without frank urethral discharge are unusual in preschool children; however, after puberty, gonorrhea may be detected in the absence of urethral discharge.8 In severe cases, cellulitis can extend down the penile shaft. Palpable inguinal adenopathy is often present.

TREATMENT AND DISPOSITION

Noninfectious balanoposthitis should be managed with careful attention to hygiene, use of warm water sitz baths, and avoidance of causative agents. Treatment of infectious balanoposthitis should be tailored to the particular infection: minor, polymicrobial infection can be treated with topical mupirocin or bacitracin; GAS infection should be treated with 10 days of ampicillin, amoxicillin, a cephalosporin, or clindamycin. Children with sexually transmitted infections should be admitted to the hospital and evaluated for sexual abuse. Indications for admission include severe infection and urinary retention.

MEATAL STENOSIS

Meatal stenosis is narrowing of the urethral meatus, usually secondary to recurrent episodes of subclinical meatitis. It can be caused by ammonia diaper irritation in circumcised boys and by recurrent balanoposthitis in uncircumcised boys. Acquired meatal stenosis more commonly occurs in circumcised boys because the foreskin in uncircumcised boys acts as a protective cover for the meatus. Congenital meatal stenosis is rare.

CLINICAL PRESENTATION AND DIAGNOSIS

Obstructive symptoms occur occasionally, including hesitancy, straining, urgency, frequency, and postvoid dribbling. An abnormal urinary stream may be seen, but urinary retention is rare. An erythematous swollen meatus is noted, often with purulent discharge. Radiographic studies are seldom necessary.

TREATMENT

Treatment of purulent meatitis includes sitz baths and the administration of oral antibiotics (e.g., cephalaxin) for 7 days.

CLINICAL PRESENTATION

Paraphimosis is accompanied by penile pain and swelling and must be differentiated from balanoposthitis, tourniquet syndrome, and the generalized edema seen with renal, cardiac, or liver failure. Irritable and inconsolable male infants should be examined for evidence of paraphimosis. Urinary obstruction can be a late finding.

TREATMENT

Emergency reduction of the foreskin back over the glans penis is the primary management of paraphimosis and should be attempted in the emergency department (ED). In the case of ischemic changes in the glans, practitioners should undertake immediate reduction and consultation with urology. Adequate analgesia is essential and, depending on the age and discomfort of the patient, can include topical medications, dorsal penile nerve block, or procedural sedation. Manual compression and reduction of the foreskin should be attempted first and can be aided by the application of ice or granulated sugar to decrease the swelling. Additional procedures include retraction with noncrushing Babcock forceps placed in the four quadrants of the foreskin or more invasive procedures that can be undertaken in consultation with urology, such as aspiration of the glans penis and a dorsal slit procedure.

BALANITIS AND BALANOPOSTHITIS

Balanitis is an infection of the glans penis, whereas balanoposthitis is an infection of the foreskin in addition to the glans. Balanitis occurs in approximately 3% of boys, usually between 2 and 5 years of age, especially if they are uncircumcised.6

Fig. 20.3  Paraphimosis in a catheterized patient with an edematous prepuce proximal to the glans. (From Zitelli BJ, Davis HW. Atlas of pediatric physical diagnosis. 5th ed. Philadelphia: Mosby; 2007.)
Urinary retention is an indication for urology consultation and hospital admission; otherwise, prompt outpatient follow-up is sufficient.

**URETHRAL STRicture**

In the United States, most cases of urethral stricture are acquired by infection and trauma. Gonococcal urethritis or infection resulting from an indwelling Foley catheter are the most common infection-related causes. In developing countries, sexually transmitted urethritis is the most common cause. Trauma can result in urethral stricture secondary to pelvic fracture and straddle injury.

**CLINICAL PRESENTATION AND TREATMENT**

Clinically, the patient has difficulty passing urine. Slowing, spraying, or dribbling of the urine stream may be noted. When patients with this condition are seen in the ED, outpatient management, including prophylactic antibiotics, is appropriate. Urethrography or voiding cystourethrography should be performed before dilation of the stricture if this procedure is necessary.

**URETHRAL FOREIGN BODY**

A urethral foreign body in older boys may have been inserted for sexual purposes. Most objects are palpable if they are in the anterior urethra. Retained foreign body should be included in the differential diagnosis of a male with signs and symptoms of recurrent urinary tract infection and no urogenital abnormalities. Most foreign bodies can be removed endoscopically.

**URETHRAL PROLAPSE**

Prolapse of the urethra is most common in young African American girls (Fig. 20.4). The prolapsed mucosa is visible and may be irritated, congested, and hemorrhagic. Though quite alarming on physical examination, it is not associated with sexual abuse. Treatment consists of sitz baths three times a day.

![Fig. 20.4](image-url) Two examples of urethral prolapse. A, Urethral prolapse in a 4-year-old girl who had bloody spotting on her underwear. B, Urethral prolapse. (A, From Behrman RE, Kliegman RM, Jenson HB. Nelson’s textbook of pediatrics. 18th ed. Philadelphia: Saunders; 2007. Fig. 544-10; B, from Zitelli BJ, Davis HW. Atlas of pediatric physical diagnosis. 5th ed. Philadelphia: Mosby; 2007. Fig. 14-50.)

- Hypoproteinemia (serum albumin <3 g/dL)
- Marked proteinuria (>40 g/m²/hr in a 24-hour period)
- Edema
- Hyperlipidemia (predominantly triglycerides and cholesterol)

**PATHOPHYSIOLOGY**

Nephrotic syndrome is classified as primary, defined as nephrotic syndrome without systemic disease, or secondary, defined as nephrotic syndrome in the presence of systemic disease. Ninety percent of children with nephrotic syndrome have the primary syndrome, the most common of which is minimal change disease (idiopathic nephrotic syndrome).
Idiopathic nephrotic syndrome is classified by its response to corticosteroids, with the majority being steroid responsive and approximately 20% being unresponsive to steroids. Lack of response to steroids portends a poor prognosis and a 50% risk for progression to end-stage renal failure.

**EPIDEMIOLOGY**

The incidence of nephrotic syndrome in children younger than 16 years is 2 to 7 per 100,000 per year, and the prevalence is 15 cases per 100,000. Boys are more likely to be affected than girls. The typical age at onset of primary nephrotic syndrome is 18 months to 6 years. Children with nephrotic syndrome at an age older than 5 years are more likely to have the secondary form. Neonates are most likely to have the congenital (Finnish) type, which is steroid resistant and generally fatal. In adolescents, nephrotic syndrome is most often associated with a primary or secondary form of an underlying nephritis.

**CLINICAL PRESENTATION**

The usual initial sign in a child with nephrotic syndrome is edema. The edema starts with early-morning periorbital swelling, often misattributed to a cold or allergies. As the edema spreads to the abdomen, trunk, and extremities, children have increasing difficulty fitting into their pants and shoes. Parents can mistake this for weight gain. The child otherwise appears well, although ascites, pleural effusion, or pulmonary edema may be present. Ascites and an edematous intestinal wall can be manifested as abdominal pain, nausea, vomiting, or diarrhea.

**COMPLICATIONS**

Complications include infection, hypercoagulability, hypovolemia, respiratory distress, and acute renal failure.

**INFECTION**

Increased susceptibility to infection results from disease-mediated impairment of the immune system, as well as treatment with immunosuppressive therapy, both of which may mask the typical signs of infection. The most common bacterial infection is peritonitis, although cellulitis, pneumonia, sepsis, and meningitis are also seen. Infection with encapsulated bacteria, such as *Escherichia coli*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*, is the main cause of death in children with nephrotic syndrome.

**HYPERCOAGULABILITY**

Hypercoagulability occurs in 3% of patients with nephrotic syndrome. Thromboembolic events can involve the arteries and veins, most commonly the pulmonary arteries, renal veins, and deep leg veins. A sudden onset of gross hematuria or renal failure should prompt investigation for renal vein thrombosis.

Because prednisone exerts an antithrombin effect, practitioners should not attempt deep venous punctures on children treated with steroids unless no alternative exists.

---

**RED FLAGS**

Do not attempt deep venous punctures in children who have nephrotic syndrome and are receiving chronic prednisone therapy because they are at increased risk for thromboembolic events.

**RESPIRATORY DISTRESS**

Pleural effusions, pulmonary edema, and massive ascites can cause respiratory distress.

**TREATMENT**

The goals of ED management are restoration of volume, treatment of symptomatic edema, and evaluation for and treatment of infectious complications. Patients in shock should be treated by isotonic hydration consisting of a 20-mL/kg bolus per hour until they are normotensive. If the patient is clinically dehydrated with hemoconcentration but not in shock, a trial of orally administered sodium-deficient fluids at twice the maintenance dose is preferable to intravenous solutions. Small amounts of oral hydration fluid should be administered frequently to avoid vomiting caused by an edematous gut.

If the patient is well hydrated and exhibits symptomatic edema or anasarca, diuretics may be warranted but should be used judiciously because these children have decreased circulating volume and are prone to thromboembolic events. Intra-venous or oral administration of furosemide, 1 to 2 mg/kg/24 hr divided into two doses, can be used. Loop diuretics are most effective, but additional diuretics such as hydrochlorothiazide or spironolactone may be administered if the response is inadequate. Diuretics are not effective with albumin concentrations of less than 1.5 g. Albumin infusions may be necessary before administration of diuretics (0.5 to 1 g/kg given as 25% salt-deficient albumin, followed by 0.5 to 1 mg/kg of furosemide).

Although patients may arrive in shock from intravascular volume depletion alone, sepsis should be excluded. Any child with nephrotic syndrome and an unexplained fever must be considered to have a bacterial infection until proved otherwise. Because persons receiving steroid therapy may not demonstrate abdominal pain or typical signs of infection, diagnostic paracentesis is necessary to exclude bacterial peritonitis in children with abdominal pain or fever in the setting of ascites. Treatment with cephalexin or ampicillin (with or without gentamicin) is recommended. Prophylactic antibiotics are not necessary unless infection is suspected, and material should be collected for culture.

The mainstay of treatment of nephrotic syndrome is steroid therapy. Generally, patients initially receive prednisone, 2 mg/kg/24 hr (maximum, 60 mg/24 hr) divided into two or three doses. Approximately 90% of patients with idiopathic nephrotic syndrome respond to steroid therapy by the end of a 4-week course, with response defined as trace or negative amounts of urine protein for 3 days. Failure to respond to steroid treatment increases the likelihood of a cause other than minimal change disease.
**Section II: Special Considerations in the Pediatric Patient**

**Disposition**

**Admission Criteria**

- Any infant with nephrotic syndrome
- Any patient with respiratory distress or shock
- Nephrotic patients with infections, unexplained fever, refractory edema, renal insufficiency, dehydration, abdominal complaints, or hemoconcentration greater than 50%
- Patients with newly diagnosed nephrotic syndrome to complete the evaluation and educate the parents about outpatient management

**Follow-up for Patients with Nonnephrotic Proteinuria**

Very few patients with dipstick proteinuria have renal disease. In the absence of edema, hypertension, oliguria, or hematuria, urinalysis repeated in 2 to 4 weeks is recommended.

**Hemolytic-Uremic Syndrome**

Hemolytic-uremic syndrome is the most common cause of acute renal failure in children, with an incidence of 1 to 10 cases per 100,000 children younger than 5 years. The mean age at diagnosis is 3 years, and the diagnosis becomes increasingly unlikely after 5 years of age. Caucasian children are more often affected than others, and there is no gender preference.

**Pathophysiology**

Hemolytic-uremic syndrome is defined by the presence of the classic triad of microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and acute renal failure (Box 20.1).

In contrast to the adult form of the disease (thrombotic thrombocytopenic purpura), the microthrombi of hemolytic-uremic syndrome are usually confined to the kidneys. Thrombotic thrombocytopenic purpura has a predominantly neurologic manifestation, a higher mortality rate, and a better response to plasmapheresis and fresh frozen plasma. Renal involvement is the defining feature of hemolytic-uremic syndrome.

The usual cause of epidemic hemolytic-uremic syndrome is the verotoxin-producing strain of *Escherichia coli* serotype O157:H7, although it can be caused by *Shigella* organisms that produce a similar toxin. Transmission is through person-to-person contact or ingestion of contaminated food, such as unpasteurized dairy products or undercooked beef. The verotoxin binds to and destroys the colonic mucosa, thereby leading to bloody diarrhea.

**Box 20.1: Hallmarks of Hemolytic-Uremic Syndrome**

- Acute renal failure
- Microangiopathic hemolytic anemia
- Fever
- Thrombocytopenia

**Clinical Presentation**

The epidemic form begins with a prodrome of nausea, vomiting, watery diarrhea, crampy abdominal pain, and occasionally fever. Bloody stools typically develop on the second or third day of symptoms. Usually between 5 and 10 days after the prodromal gastroenteritis, there is a sudden onset of pallor, listlessness, irritability, and oliguria because of development of the classic triad (MAHA, thrombocytopenia, renal failure). Additional signs on clinical examination may include dehydration, edema, hypertension, petechiae, hepatosplenomegaly, jaundice, and neurologic manifestations (obtundation, hemiparesis, seizures, brainstem dysfunction).

Gastrointestinal complications such as toxic megacolon, ischemic colitis, intussusception, and perforation are also possible. Pancreatic insufficiency from microinfarction in the pancreas can lead to permanent insulin-dependent diabetes mellitus.

**Diagnostic Testing**

Hemolytic-uremic syndrome is diagnosed clinically by symptoms coupled with consistent laboratory findings. The presence of MAHA is necessary to establish the diagnosis. The peripheral blood smear demonstrates signs of a microangiopathic process: teardrop cells, helmet cells, spherocytes, and burr cells.

A complete blood count may show leukocytosis, profound anemia (with hemoglobin levels of 5 to 9 g/dL), and mild to moderate thrombocytopenia (platelet counts are generally around 40,000/mm³).

C-reactive protein levels may be elevated. The coagulation profile is usually normal, and although serum fibrin split products might be elevated, fulminant disseminated intravascular coagulation is rare. Chemistry abnormalities include hyponatremia, hyperkalemia, azotemia, metabolic acidosis, hyperbilirubinemia, low total protein as a result of proteinuria, and elevated lactate dehydrogenase. Urinalysis often shows hematuria, proteinuria, and pyuria. Granular and hyaline casts are seen in the urine sediment.

Specific serologic testing for antibodies to the lipopolysaccharide of *E. coli* O157:H7 is necessary because routine stool cultures may not always detect the bacteria or verotoxin.

**Treatment and Disposition**

Severe anemia, defined as a hemoglobin concentration lower than 6 g/dL, requires transfusion of packed red blood; platelet transfusion is recommended only with active bleeding or in preparation for a required invasive procedure.

Indications for dialysis in children with hemolytic-uremic syndrome are similar to those with renal failure: signs and symptoms of uremia, azotemia, severe fluid overload, and electrolyte disturbances not responsive to medical therapy. Rehydration should be done slowly to avoid fluid overload.

Hypertension is generally responsive to the administration of calcium channel blockers, labetalol, captopril, hydralazine, or in refractory cases, nitroprusside. Seizures will respond to benzodiazepines and phenytoin; however, hyponatremic seizures do occur and should be evaluated for and treated with...
hypertonic 3% saline. Plasmapheresis or fresh frozen plasma infusion has no proven efficacy for diarrhea-associated hemolytic-uremic syndrome but may be useful for recurrent, inherited, drug-induced, or idiopathic hemolytic-uremic syndrome, especially in those with neurologic involvement. The role of antibiotics remains controversial. One theory is that antibiotics may enhance the release of verotoxin from the bacteria; therefore, they are not generally recommended. Antimotility agents should be avoided because they may cause toxic megacolon.

Patients require admission and pediatric nephrology consultation. The prognosis is poor in patients who have nondiarrheal forms of the disease, are younger than 1 year, or have prolonged anuria, hypertension, or severe central nervous system disease. In general, mortality is less than 5%, and an additional 5% will have long-term consequences of end-stage renal disease or stroke.

**ACUTE GLOMERULONEPHRITIS**

Acute glomerulonephritis refers to a spectrum of inflammatory renal disorders characterized by hematuria and proteinuria.

**PATHOPHYSIOLOGY**

The most common form of acute glomerulonephritis in children occurs 1 to 3 weeks after a throat or skin infection with group A β-hemolytic streptococci. The humoral immune response to the infection leads to the deposition of antibodies, activation of complement, and ultimately, inflammation within the glomeruli. The latency period for both the pharyngeal and cutaneous forms can be as long as 6 weeks. Anuria and renal failure occur in 2% of patients.

**CLINICAL PRESENTATION**

The signs and symptoms of acute glomerulonephritis are presented in Box 20.2.

The diagnosis is usually made in the ED based on the patient’s history. The typical patient is a 5- to 6-year-old boy who is brought to the ED 1 to 2 weeks after a preceding streptococcal infection or 3 to 6 weeks after the onset of pyoderma. The patient has had a sudden onset of brown, tea-colored, or grossly bloody urine; decreased urine output; and edema involving the face, periorbital areas, and extremities. On examination, hypertension (both systolic and diastolic) may be found. Some children may be asymptomatic except for the change in urine color. Rarely, patients with advanced disease may have congestive heart failure, hypertensive encephalopathy, or other life-threatening complications of renal failure.

**DIAGNOSTIC TESTING**

Urinalysis is the single most important test in categorizing glomerulonephritis. Proteinuria is almost always more than 2+ on the dipstick, which indicates that the measured protein is not merely secondary to hematuria. In 60% of cases, red blood cell casts are seen on microscopic analysis. Hyaline granular casts and pyuria are common. Urine culture should always be performed.

Serologic testing can confirm streptococcal infection. Anti-streptolysin O titers are elevated in 90% of cases, peak at 10 to 14 days, and return to normal after 3 to 4 weeks; antihyaluronidase titers peak at 3 to 4 weeks. In patients with skin infections, anti-DNAse-B antibodies can be measured.

**TREATMENT AND DISPOSITION**

The key to a successful outcome is early diagnosis in the ED and treatment of life-threatening emergencies such as hyperkalemia, hypertension, and congestive heart failure. Management of patients with nephritis is primarily supportive, with restricted fluid and sodium intake. Antibiotics are required for ongoing infectious processes.

Any child who is oliguric or hypertensive should be hospitalized and scheduled for nephrology consultation. Otherwise, discharge from the ED is reasonable, with instructions for a low-sodium diet and close follow-up with the pediatrician. The family should be advised to monitor the patient’s urine output and weight and observe for signs of congestive heart failure or hypertension. In general, the prognosis is excellent. Approximately 80% to 90% of these children recover without any persistent renal abnormalities except for microscopic hematuria, which may persist for up to 18 months.

**IgA NEPHROPATHY**

IgA nephropathy, also known as Berger disease, is the type of glomerulonephritis most commonly diagnosed in adolescence. This disease accounts for up to 25% of cases of glomerulonephritis in Asia and Europe and up to 10% in the United States.

**CLINICAL PRESENTATION AND DIAGNOSIS**

The classic finding is hematuria or proteinuria with a preceding upper respiratory infection. The diagnosis is confirmed by a renal biopsy specimen with deposition of IgA in the mesangium.

**TREATMENT AND DISPOSITION**

Gross hematuria resolves spontaneously within days without serious sequelae in 85% of patients. Because the prognosis is good in most patients without significant proteinuria or renal dysfunction, treatment is not usually needed. However,
proteinuria, hypertension, or renal insufficiency portends a poor prognosis and should be managed in consultation with nephrology.

HENOCHE-SCHÖNLIN PURPURA WITH RENAL INVOLVEMENT

Henoch-Schönlein purpura is the most common form of small-vessel vasculitis in childhood. Most patients have the triad of abdominal pain, arthritis, and purpura. A third of the patients have renal involvement, 80% of whom will have asymptomatic hematuria. The populations most affected are school-age children and young adults, and it occurs more commonly in Caucasians and males. One third to three fourths of patients have a preceding respiratory infection.

CLINICAL PRESENTATION

Usually occurring within the first month of illness, renal involvement develops in approximately one third of patients, with progression to end-stage renal disease in less than 1%. Predictors of a poor prognosis include late onset of renal involvement in older children and massive proteinuria; 20% of such cases result in end-stage renal failure. Approximately 50% of patients in whom nephritic syndrome with Henoch-Schönlein purpura develops will progress to end-stage renal disease within 10 years.

The diagnosis is made clinically and not based on laboratory studies.

TREATMENT

Prednisone, 1 to 2 mg/kg/day for 2 weeks (max 60 mg/day), with tapering of the dose over a 2-week period, has been shown to improve gastrointestinal and joint symptoms and lessen the severity of nephritis. About one third of affected patients will have a recurrence of at least one symptom. Fortunately, most patients recover quickly in several weeks with supportive treatment.

RENAAL TUBULAR ACIDOSIS

The normal response to acidemia is to reabsorb all the filtered bicarbonate and to increase excretion of hydrogen, primarily by excreting ammonium ions in urine.

Renal tubular acidosis occurs when the renal tubules are unable to perform these functions. Accumulation of ammonium ions and subsequent metabolic acidosis can cause growth retardation, kidney stones, bone disease, and progressive renal failure.

Four subtypes of renal tubular acidosis are recognized:

Type 1—distal (classic form)
Type 2—proximal (bicarbonate wasting)
Type 3—a combination of types 1 and 2
Type 4—hyperkalemic (rare in children)

Types 1 and 2 are encountered most frequently in children. The diagnosis of all types requires a serum electrolyte panel and urinalysis with urine pH.

TYPE 1 RENAL TUBULAR ACIDOSIS

Distal renal tubular acidosis results from a defect in the tubular transport of hydrogen in the distal nephron. The most common form in children is hereditary, but it can be a complication of systemic diseases seen more commonly in adults such as Sjögren syndrome, lupus erythematosus, and hyperparathyroidism. Patients have failure to thrive, anorexia, vomiting, and dehydration. Hyperchloremic metabolic acidosis and hypokalemia may be seen. Hypercalciuria can be manifested as rickets, nephrocalcinosis, nephrolithiasis, and renal failure. Urine pH usually exceeds 6.5.

The classic diagnostic test for distal renal tubular acidosis is an acid load from ammonium chloride; however, this is a tedious test that can generate severe acidosis. Distal renal tubular acidosis can be permanent, but children may outgrow it by the time that they are of school age. Treatment is focused on correction of the acidosis with sodium bicarbonate or sodium citrate, which may also prevent kidney stone formation. Target serum HCO₃ levels should be between 20 and 22 mEq/L in infants and between 22 and 26 mEq/L in children.

TYPE 2 RENAL TUBULAR ACIDOSIS

Proximal renal tubular acidosis is the most common form found in children. Because approximately 85% to 90% of bicarbonate reabsorption occurs in the proximal tubules, proximal renal tubular acidosis is characterized by an alkaline urine (usually pH >7), loss of bicarbonate in urine, and mildly reduced serum bicarbonate concentration.

Proximal renal tubular acidosis can result from inherited disorders (hereditary fructose intolerance, Wilson disease, cystinosis, Fanconi syndrome, Lowe syndrome), exposure to medications (chemotherapy agents, acetazolamide, sulfonamides), anatomic abnormalities (obstructive uropathy, reflux), or exposure to heavy metals. Treatment consists of alkaline therapy with citrate solutions (Bicitra, Polycitra) or sodium bicarbonate. Potassium supplements may also be required because the added sodium load of the sodium bicarbonate may increase potassium loss in the distal tubule.

URINARY RETENTION

Urinary retention is defined as failure to urinate for more than 12 hours. More than 90% of all newborns void within the first 24 hours of life and 99% within the first 48 hours. In male children, posterior urethral valves are the most common cause of retention. Other causes include urethral polyps, urethral stricture, urethral diverticulum, meatal stenosis, and fecal impaction. In female infants, the differential diagnosis includes prolapsing ureterocele, urethral prolapse, and foreign bodies. Infections, medications, spinal cord abnormalities, and sexual abuse can cause retention in both male and female children. Diagnostic tests in the ED include blood urea nitrogen, creatinine, and urinalysis.

REFERENCES

Prepubertal girls are more sensitive to a variety of chemical, physical, and microbiologic irritants. The normal hymen looks thin, with an average opening of about 4 mm. However, there is great variability in normal hymenal shape, ranging from imperforate to multiple small fenestrations to oval, round, or stellate openings (Fig. 21.1). Abnormal findings that may correlate with vaginal penetration include lacerations of the hymen or a thickened hymen with rolled edges. These findings are extremely difficult to differentiate from normal variations, and photos should always be taken if sexual abuse is suspected. Neonates have swollen labia and thick, moist vaginal epithelium for several weeks after birth, but most prepubertal girls have smooth pink vaginal mucosa and a pale vulva that barely covers the clitoris.

**PRESENTING SIGNS AND SYMPTOMS**

The chief complaints of children with gynecologic problems include vaginal discharge or bleeding, itching or rubbing of the genitals, dysuria or refusal to void, or a foul genital odor noted by caregivers. The initial differential diagnosis can be guided by the predominant complaints (Box 21.1). A calm, professional, thoughtful approach is essential to allow parents to discuss their concerns, enable a physical examination, and appropriately treat the patient. Vulvovaginitis, for example, can cause vaginal discharge or bleeding, itching or pain, urinary retention, abnormal appearance noted by caregivers, and concerns about possible sexual abuse.

The approach to pediatric gynecologic problems must take into account the developmental and psychologic state of the patient. Children zealously guard autonomy over their bodies. In addition, little girls are socialized to hide their genitals and will resist examination for various reasons throughout developmental stages—it is important to help them overcome their fear, embarrassment, or anxiety. It is helpful, when attempting to make the child comfortable with the examination, to speak directly to the child in language appropriate for her age (see the Tips and Tricks box). In teaching hospitals, try to coordinate care so that the examination is performed only once.

**EPIDEMIOLOGY**

Gynecologic concerns are common but nonetheless anxiety producing in prepubertal girls. Vulvovaginitis is the most common gynecologic problem affecting prepubertal girls and is responsible for the largest number of health care visits. Pediatric sexual abuse affects more than 100,000 children a year, and many of these girls will be taken to the emergency department (ED) for initial evaluation. Many parents going to the ED have spoken or unspoken concerns about sexual abuse that need to be addressed.

**PATHOPHYSIOLOGY**

Pediatric gynecologic problems differ from those of adult women chiefly because the vaginal mucosa is thin, dry, and easily irritated in the absence of estrogen. This makes prepubertal girls more sensitive to a variety of chemical, physical, and microbiologic irritants. The normal hymen looks thin, with an average opening of about 4 mm. However, there is great variability in normal hymenal shape, ranging from imperforate to multiple small fenestrations to oval, round, or stellate openings (Fig. 21.1). Abnormal findings that may correlate with vaginal penetration include lacerations of the hymen or a thickened hymen with rolled edges. These findings are extremely difficult to differentiate from normal variations, and photos should always be taken if sexual abuse is suspected. Neonates have swollen labia and thick, moist vaginal epithelium for several weeks after birth, but most prepubertal girls have smooth pink vaginal mucosa and a pale vulva that barely covers the clitoris.

**KEY POINTS**

- Prepubertal girls have thin, sensitive vaginal mucosa that is easily irritated.
- If speculum examination is necessary in a young girl, examination under anesthesia should be considered.
- Parents of young girls taken to the emergency department because of gynecologic complaints are often worried about the possibility of sexual abuse but may not verbalize their concern until appropriate questions are asked.
- Most pediatric gynecologic complaints are not related to abuse.
- Most sexually abused children have no abnormalities on examination.
- Emergency department evaluation of possible sexual abuse should focus on identification of patients who require urgent treatment, urgent collection of evidence, or protective custody.

**PRESENTING SIGNS AND SYMPTOMS**

BOX 21.1 Differential Diagnosis of Gynecologic Disorders in Children

Discharge
Physiologic leukorrhea in newborns and early puberty
Foreign body
Sexually transmitted infection
Sexual abuse

Pain or Itching
Nonspecific vulvovaginitis (chemical or physical irritants)
Group A Streptococcus infection
Shigella infection
Pinworm (Enterobius vermicularis) infestation
Foreign body
Genital warts
Behçet syndrome
Lichen sclerosus et atrophicus
Sexual abuse

Bleeding
Trauma
Urethral prolapse
Foreign body
Lichen sclerosus et atrophicus
Sexual abuse
Endocrine abnormalities
Genital warts
Genital tumor
Withdrawal bleeding (newborn)

SEXUAL ABUSE

ED evaluation of possible sexual abuse should focus on identifying patients who require urgent treatment, urgent collection of evidence, or protective custody (Fig. 21.2). Open-ended questions by the emergency practitioner (EP) will allow the parents to voice their concerns about possible molestation (this should be done away from the child). When interviewing the patient, history taking should be limited to open-ended questions phrased in child-appropriate language, such as “How did you get this ouchie?” Do not make suggestions that the child may follow in an attempt to please. Do not direct, lead, or ask questions with embedded information because such information can appear in the child’s later responses. Formal interviewing and complete examination are best minimized in the ED and instead carried out by trained personnel. ED providers should be aware of local resources and if possible refer children to a designated child sexual abuse evaluation center.

If abuse is alleged within the past 72 hours, collection of evidence should be undertaken as soon as possible. In studies of forensic evidence collection in prepubertal sexual assault cases, the majority of usable evidence is found on clothing and linen. In one large study of prepubertal sexual assault victims, no swabs were positive for blood after 13 hours or for semen or sperm after 9 hours. ¹

A brief physical examination of the vulva, vagina, and anal area should be undertaken, as described previously. The chief
by applying labial traction in two directions—both apart and apart and down (Fig. 21.4).

Some children may be more comfortable hugging their knees to their chest (knee-chest position); labial traction will also be necessary when using this position. In a variation of the knee-chest position, the child rises on her hands and knees and then puts her head down on the examination table (see Fig. 21.3, B).

If the child is uncooperative, it is a matter of clinical judgment whether the importance of the examination is worth the stress caused by it. Referral to a child sexual abuse center or examination under anesthesia should be considered.

The EP should avoid directly touching the sensitive mucosa.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**LABIAL ADHESIONS**

In prepubertal girls, a small section or the entire labia majora may be fused in the midline (Fig. 21.5). Labial adhesion is a self-limited condition and the labia will open with estrogenization at puberty. Though usually asymptomatic, some girls with labial adhesions may have an increased propensity for urinary tract infections. Occasionally, labial adhesions will

**GENITAL EXAMINATION**

Infants and young toddlers can usually be examined easily if positioned supine in the frog leg position (Fig. 21.3). Prepubertal girls can be examined in either the supine or the prone position. If the child is cooperative, she can lie in the supine position with the feet together and the knees bent and placed apart in the frog-leg position. Visualization can be improved
Fig. 21.4 Examination of the vulva, hymen, and anterior vagina by gentle lateral retraction (above) and gentle gripping of the labia and pulling anteriorly (below). (From Emans SJ, Office evaluation of the child and adolescent. In: Emans SJ, Laufer MR, Goldstein DP, editors. Pediatric and adolescent gynecology. 4th ed. Philadelphia: Lippincott-Raven; 1998.)

Fig. 21.5 A, Labial adhesions in a 2½-year-old girl. Two tiny openings exist—one beneath the clitoris and another near the middle line of fusion. B, Appearance of the same child after 10 days of local application of estrogen ointment. (From Dewhurst CJ. Gynaecological disorders of infants and children. Philadelphia: Davis; 1963.)

Fig. 21.6 Imperforate hymen distended by hematocolpos. (From Baramki TA. Treatment of congenital anomalies in girls and women. J Reprod Med 1984;29:376.)

IMPERFORATE HYMEN

Imperforate hymen is a rare condition and may be encountered at any age. Neonates and prepubertal girls may have a bulging hymen noted during diaper changing or bathing. More classically, pubertal or postpubertal girls are evaluated for abdominal pain and absence of menses despite the development of breasts and pubic hair. Findings on physical examination may be normal, or a bulging hymen with a dark (bloody) fluid collection behind it may be seen (Fig. 21-6). Ultrasonography will confirm the diagnosis of hydrometrocolpos (a fluid and blood-filled uterus and vagina). A similar finding may be present with a transverse vaginal septum, but in this condition the hymen is patent.

VAGINAL DISCHARGE WITHOUT ASSOCIATED SYMPTOMS

Physiologic leukorrhea is a manifestation of the effect of estrogen on the vaginal mucosa. Otherwise asymptomatic discharge may be seen in neonates and begins again 1 to 2 years before menarche. Many girls or their parents will complain of a white or yellowish discharge found on the girl’s underwear. Unlike vulvovaginitis, no irritation or pain is present. In sexually active girls, wet preparations and cultures may be necessary to rule out sexually transmitted infection. After infancy and before early puberty, the EP should consider the possibility of a foreign body in girls with a complaint of vaginal discharge, even without other symptoms.

VULVOVAGINITIS

Vulvovaginitis (vaginal discharge with irritation and itching) is a common condition in prepubertal girls. Common complaints include vaginal discharge, itching, redness, dysuria, and bleeding (Fig. 21-7). The prepubertal vaginal mucosa is thin, dry, and very sensitive to minor irritants. Poor hygiene, tight clothing, perfumes and bubble baths, and overzealous wiping are common causes of vulvar irritation and inflammation.

In addition, a variety of infectious agents can cause vulvovaginitis. Pinworm (Enterobius vermicularis) infestation
Fig. 21.7  Algorithm showing critical questions and priority actions for pediatric vaginitis. HPV, Human papillomavirus; OR, operating room.
should be suspected in girls with pronounced itching, particularly at night. Vulvovaginitis may be caused by group A β-hemolytic streptococcal infection and should be suspected when the vulvar area is beefy red or if the patient has systemic signs of streptococcal infection (fever, scarlatin rash). A retrospective study found that 21% of prepubertal girls with vulvovaginitis were culture positive for group A streptococcal infection. Streptococcal infection is more likely in older girls (school age) and in those with recent exposure to other children with streptococcal pharyngitis. Rarely, Shigella can cause a similar infectious vagnitis. Yeast does not thrive in the dry mucosa of prepubertal girls, and vaginal candidiasis is extremely rare.

The EP should inquire about contact with individuals who have infectious pharyngitis or diarrhea and send culture swabs from the vagina for analysis when suspicion exists. The swabs should be moistened with nonbacteriostatic saline before sampling to reduce the patient’s discomfort.

Rarely, vulvovaginitis may be caused by sexual abuse or sexually transmitted infection. If a sexually transmitted infection is suspected, culture specimens for gonorrhea (plated on chocolate agar) and Chlamydia (Dacron swab in viral transport medium) should be obtained, in addition to DNA probe testing if warranted (in many areas, DNA probe testing is not admissible in court).

Vulvar itching and bleeding can be caused by genital warts. If warts are seen on examination, it may be an indication of sexual abuse, but genital warts could result from nonsexual contact with common warts. Vertical transmission of genital human papillomavirus infection from the birth canal may give rise to condyloma acuminatum after a period of several months. Lichen sclerosus et atrophicus is an autoimmune condition marked by thinned and bleeding labia. The classic finding is a figure-of-eight pattern of hypopigmentation and skin breakdown around the labia and anus. Often mistaken for trauma from sexual abuse, this condition is potentially disfiguring. The patient should be referred to a dermatologist for evaluation and initiation of treatment, which usually consists of potent topical steroids or testosterone cream.

### Vaginal Foreign Bodies

Patients with vaginal foreign bodies may have complaints of itching, pain, and bloody or foul-smelling vaginal discharge. Toilet paper is overwhelmingly the most common type of a vaginal foreign body. Insertion of other objects may be the result of exploratory play in very young, developmentally delayed, or sexually abused girls. The possibility of sexual abuse should be considered in girls with vaginal foreign bodies other than toilet paper.

### Vaginal Bleeding Without Irritation

Precocious menarche is defined as cyclic bleeding before the age of 8 years. Precocious puberty should be suspected when vaginal bleeding is accompanied by breast swelling or growth of pubic hair. Most precocious puberty is idiopathic but may occasionally be a sign of hormone production by ovarian or pituitary tumors.

Urethral prolapse is characterized by dysuria and blood in the patient’s underwear or on toilet paper. It is most commonly seen in prepubertal African American girls. Examination reveals a doughnut-shaped eversion of dark red mucosa at the urethral meatus, which may cover the vaginal introitus.

### Treatment

#### Labial Adhesions

If treatment of labial adhesion is necessary, an estrogen-containing cream may be applied to the fused area. In more than 90% of cases, the adhesions will be released within a few weeks of treatment; however, fusion often recurs. After release of adhesions, a barrier cream such as Vaseline or zinc oxide should be applied to the labia several times a day to prevent recurrence. Parents should be told that topical estrogen is easily absorbed and may cause vaginal hyperpigmentation or breast swelling, which should resolve after discontinuation of the cream.

#### Imperforate Hymen

Referral should be made to a gynecologist for incision of an imperforate hymen or resection of a transverse septum.

#### Vulvovaginitis

Treatment of vulvovaginitis should be tailored to the underlying cause. For the majority of girls with nonspecific vulvovaginitis, sitz baths and education about hygiene will suffice. Girls with severe dysuria or urinary retention may be able to urinate in the tub during a sitz bath (see the Patient Teaching Tips box). Streptococcal infection can be treated with oral penicillin, clindamycin, or a macrolide antibiotic for 10 days. Shigella infection can be treated with amoxicillin or trimethoprim-sulfamethoxazole. Pinworm infestation is easily treated with chewable mebendazole and a repeat dose in 2 weeks. Children with genital warts should be referred to dermatology or pediatric gynecology services for treatment.

#### Vaginal Foreign Bodies

Vaginal foreign bodies will often be visible on physical examination without the use of a speculum and can be removed under direct visualization or by irrigation. To perform irrigation, instruct the patient to sit on a bedpan or an absorbent pad. Insert a small catheter or feeding tube several centimeters into the vagina and flush warm saline solution through a large syringe until confident that no further foreign body remains. If unable to remove the foreign body by irrigation in the ED or if a speculum examination is required, it is advisable to schedule an examination under anesthesia and treatment by a pediatric gynecologist.

#### Vaginal Bleeding or Discharge Without Irritation

Treatment of physiologic leukorrhea consists of only reassurance.

In a patient believed to have precocious menarche, the EP should document staging of pubertal development and palpate for abdominal masses. If an abdominal mass is palpated, ultrasonography or abdominal computed tomography should be performed. Girls with signs of precocious puberty should be referred to their primary care physician or a pediatric endocrinologist.

Urethral prolapse will generally reduce itself if left alone. Conservative treatment with sitz baths should be initiated in the ED, with primary care follow-up to consider the need for estrogen cream or surgical excision in recalcitrant cases.
**TRAUMA**

Straddle injuries involving the vulva and vagina result from falls onto playground equipment, bicycles, or furniture. Although straddle injuries require sensitive handling, they are no more likely than other traumatic injuries to be the result of sexual abuse. If the history does not correlate with the findings on physical examination, further investigation for child abuse is indicated. Frequent findings with straddle injury include abrasions or bruising of the labia, lacerations of the labia or posterior fourchette, tears of the vagina and hymen, and vulvar hematomas. If the extent of the internal injury is at all in question, referral to a pediatric gynecologist or pediatric surgeon for examination under anesthesia should be considered. Other indications for referral include tense vulvar hematomas, which may require drainage to avoid tissue necrosis, and lacerations requiring surgical closure. For minor trauma not requiring further referral, ensure that the patient is able to urinate before she is discharged from the ED.

**NEWBORN VAGINAL DISCHARGE AND BREAST SWELLING**

Maternal estrogen is the cause of most newborn gynecologic complaints. Physiologic leukorrhea appears as a white or cream-colored vaginal discharge. Newborn girls often have a smear of blood on their diaper, the result of endometrial sloughing after withdrawal of maternal estrogen. Parents occasionally mistake a peach-colored smear of urate crystals on the diaper for blood. Urate crystals are commonly seen in the first several days of life, most often in breastfed babies who are mildly dehydrated.

Maternal estrogen can also cause noticeable swelling of the breast buds in both male and female infants. Expression of milk on palpation (witch’s milk) is possible, but manipulation of the swollen tissue should be discouraged because it may cause infection. The swelling should be examined carefully for signs of infection; it should be mobile and without redness, warmth, or undue tenderness.

Neonatal mastitis is a potentially serious bacterial infection that requires aggressive work-up and treatment like any other infection in this age group. Treatment consists of antistaphylococcal antibiotic coverage. Neonatal mastitis can develop into an abscess requiring incision and drainage. Consultation with a pediatric surgeon should be considered if an incision near the breast bud is required because damage to the breast bud can lead to a poor cosmetic outcome of the breast in later life.

**BREAST DISORDERS IN OLDER CHILDREN**

Both male and female children and adolescents may experience some degree of breast bud swelling in early puberty, before the growth spurt and development of adult body hair. The physical examination should include palpation and a description of the breast swelling, a description of any axillary and pubic hair, and—in male patients—palpation of the testicles.

Normal breast tissue should be rubbery, firm, smooth, mobile, and somewhat tender. Gynecomastia can be exceptionally distressing for boys, who should be told that this is a normal male response to hormonal surges and is not evidence of any developmental or sexual abnormality. In most cases it resolves after sexual maturity. Rarely, boys with marked gynecomastia may need referral for cosmetic surgery.
A breast mass in teenage girls is uncommon but causes considerable psychologic distress. Although breast cancer is extraordinarily rare in adolescents, it is usually the prime concern of young girls with a breast mass. Most adolescent breast masses are cystic and caused by fibrocystic breast disease, as in adults. Fibroadenomas are the most common solid masses seen in teenagers. Most adolescent girls with a breast mass should be referred to their primary physician for reexamination later in the menstrual cycle. Suspected abscesses may be drained by needle aspiration or treated conservatively with antistaphylococcal antibiotics. If imaging is necessary, ultrasonography is most helpful to differentiate cystic from solid masses and support needle aspiration of fibrocystic disease or abscesses.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Nearly all children with gynecologic and breast problems can be treated as outpatients and referred to their primary care physician for follow-up. Newborns with mastitis and fever may require hospital admission for evaluation of sepsis and intravenous antibiotic administration.

Older children may require admission for treatment under anesthesia for drainage of tense vulvar hematomas, repair of lacerations, incision of an imperforate hymen, or removal of foreign bodies. Available surgical services vary, but care can be provided by pediatric general surgery, gynecology, or rarely urology services. All prepubertal girls requiring internal pelvic examination should be referred to a pediatric specialty center for examination under anesthesia.

Suspicion of child sexual abuse mandates referral to child protective services and an experienced evaluation center. In cases of suspected abuse in which the home environment is not safe, children may require admission to the hospital or discharge to temporary foster care to ensure their safety pending investigation by child protective services.

Pediatric Abdominal Disorders

Russ Horowitz

Wilms tumor arises from the renal parenchyma and in most cases is asymptomatic. Neuroblastoma develops from the adrenal gland or along the sympathetic chain and may thus be manifested as either a midline or flank mass. It is an aggressive malignancy and has often metastasized at diagnosis. Ultrasonography and computed tomography (CT) are useful for investigation of abdominal lesions. A pediatric surgeon and oncologist should be consulted early for management of abdominal tumors.

GASTROINTESTINAL BLEEDING

As a general rule, gastrointestinal (GI) bleeding is not usually as severe in children as in adults. In particular, the vast majority of cases of neonatal GI bleeding are benign. The first step in evaluation is to confirm that the suspicious material found in the stool or diaper is actually blood by performing a guaiac filter test for occult blood. Children routinely consume both foods (watermelon) and liquids (antibiotics such as cefdinir, fruit punch, and other juices) that turn the stool red, which may falsely lead both parents and health care workers to believe that GI blood loss is occurring. The benign pink or orange urate crystals in the urine of some neonates and young children are sometimes mistaken for blood when seen in diapers. Urinary tract infections and urethral prolapse may also result in deposition of blood in the diaper that could be confused with GI blood.

Upper GI bleeding produces dark brown, black, or simply heme-positive stool. However, because of the fast transit time in neonates, some upper GI bleeding may be bright red. The most common cause is swallowed maternal blood, acquired either during delivery or as a result of breastfeeding from irritated or cracked nipples.

Esophageal varices are rare in children. In contrast to adults, in whom primary hepatic disease is the leading cause, the most likely cause of varices in children is splanchnic and portal vein obstruction. Varices may develop secondary to umbilical vein catheterization, dehydration, sepsis, or omphalitis. Less common causes are hepatic parenchymal conditions such as biliary cirrhosis secondary to biliary atresia, cystic fibrosis, α1-antitrypsin deficiency, and hepatitis. Early onset of inflammatory bowel disease occurs in the teenage years and is uncommon in younger children.

Perirectal skin breakdown and external rectal fissures both produce blood-streaked stool and are easily identifiable on

KEY POINTS

- The most common cause of intestinal obstruction in patients younger than 6 years is intussusception.
- Henoch-Schönlein purpura is a vasculitis that causes abdominal pain, purpura, and arthritis. Renal involvement is present in up to 50% of cases and is manifested as microscopic hematuria and proteinuria.
- Bilious emesis in infants is suggestive of highly morbid conditions such as malrotation with volvulus, necrotizing enterocolitis, sepsis, or small bowel obstruction.
- In up to 90% of children younger than 2 years with appendicitis, the appendix has perforated by the time of diagnosis. These patients will be found to have generalized peritonitis and shock more often than older children or adults with appendicitis.

EPIDEMIOLOGY

Abdominal pain is a common complaint in children. Up to 25% of children will experience discomfort severe enough to interfere with activity, and annually, one in every seven children in the United States will visit a physician because of abdominal complaints, yet most will have no organic cause identified. Between 2% and 4% of all pediatric outpatient visits are related to abdominal complaints. Discerning the presence of serious underlying disease can be challenging. This chapter describes several of the most significant pathologic abdominal conditions in pediatric patients.

ABDOMINAL MASSES

Obstructive uropathy and renal cysts are the most likely causes of abdominal distention in infancy. Abdominal tumors are slow growing and usually recognized incidentally (e.g., when a parent or physician feels an abdominal mass). The two most common malignancies are Wilms tumor and neuroblastoma. The majority of affected children are younger than 5 years.
physical examination. Sitz baths and stool softeners are useful in treating rectal fissures.

Emergency department (ED) management of GI bleeding is directed at fluid and blood resuscitation.

### MECKEL DIVERTICULUM

A Meckel diverticulum is the most common omphalomesenteric remnant. The most frequently observed finding is painless rectal bleeding, which occurs as a result of ulceration of the diverticulum or neighboring mucosa by the ectopic tissue. The ectopic tissue is gastric in origin in more than 80% of cases, but it may be pancreatic as well. Symptoms usually occur within the first 2 years of life, and in the majority of affected individuals it is diagnosed by 20 years of age (Box 22.1). A Meckel diverticulum can act as a lead point in intussusception. The diagnostic study of choice is a radiolabeled bleeding study called a Meckel scan. Definitive therapy is surgical excision.

### INTUSSUSCEPTION

Intussusception occurs when one loop of intestine invaginates into another. Intussusception of the mesentery can also occur and result in edema and vascular congestion. It is the most common cause of intestinal obstruction in children younger than 6 years. The ileocolic region is most often involved. Intussusception is usually manifested in children 6 to 18 months old, with a peak occurrence at 10 to 12 months. The vast majority of cases in children younger than 3 years are idiopathic. One etiologic theory is that inflammation of Peyer patches within the intestine acts as a lead point for the intussusception. In children older than 5 years, a true lead point is usually located on the buttocks and lower extremities. It is significant reflux of contrast material. Such intussusceptions are difficult to visualize and reduce via enema unless there is significant reflux of contrast material. Such intussusceptions are associated with Henoch-Schönlein purpura (HSP), in which the vasculitis acts as a lead point.

Early on, stools test guaiac negative. If bowel ischemia ensues, frank blood mixed with mucus gives the stool a currant jelly appearance.

Some children have only lethargy, which can delay the diagnosis. The most commonly confused entity is constipation because of the similar pattern of colicky abdominal pain. These two conditions can easily be differentiated with a plain abdominal radiograph.

The history is the best guide to the diagnosis of intussusception. On abdominal palpation the right lower quadrant may be empty because the cecum has rotated out of its standard position. The actual intussusception may be palpated as a sausage-shaped mass in the right upper quadrant. Normal physical findings should not dissuade the examiner from proceeding with investigation because most children appear normal between episodes. No laboratory studies are available to confirm the diagnosis, and guaiac test–positive stool is a late finding. Abdominal radiographic findings are most often normal, but a mass may be seen in the right upper quadrant.

Intussusception can be reliably diagnosed with ultrasound. Enemas are both diagnostic and therapeutic. Intussusceptions that cannot be reduced by enema must be reduced surgically. Up to 10% of cases recur, most often within 24 hours. After reduction, the child must be admitted to the hospital for a 24-hour observation period.

Children with a history and physical findings suspicious for intussusception must be evaluated quickly because the passage of time increases both the edema and the difficulty of achieving reduction. A pediatric surgeon should be contacted before the child undergoes attempted enema reduction in case of failure or perforation. Ileocolic intussusceptions may be difficult to visualize and reduce via enema unless there is significant reflux of contrast material. Such intussusceptions are associated with Henoch-Schönlein purpura (HSP), in which the vasculitis acts as a lead point.

### HENOCH-SCHÖNLEIN PURPURA

HSP is a vasculitis that predominantly affects the capillaries and small vessels. It occurs most commonly in school-age children, with the classic triad consisting of abdominal pain, purpura, and arthritis. Elevations of immunoglobulin A (IgA) are detectable in the blood, along with immune complex deposition in the skin and glomeruli. There is no known etiology, but HSP has often been found to occur after upper respiratory infections. Recurrences are seen in up to 50% of cases.

Abdominal pain occurs in half the patients and is most frequently colicky in nature. Intussusception should be strongly considered in children with guaiac test–positive or frankly bloody stools accompanied by severe pain. The subtype of intussusception associated with HSP is often ileoileal, which is difficult to visualize and reduce with a contrast enema. CT is the imaging modality of choice for ileoileal intussusception associated with HSP, and reduction must often be achieved surgically.

The rash associated with HSP is petechial, purpuric, and usually located on the buttocks and lower extremities. It is seen in dependent areas, so the scrotum and hands may also be affected. In younger children, the rash is displayed on the
dorsal surfaces of the extremities, trunk, and head. The lesions are palpable and appear and progress like common bruises.

Arthritis occurs in two thirds of patients and most often involves the large joints of the lower extremities. The knees and ankles may be edematous and tender to palpation or with movement. Joint pain may be so severe that it interferes with ambulation.

Renal involvement occurs in 25% to 50% of patients and is usually manifested as microscopic hematuria and proteinuria.

The diagnosis of HSP is based on the characteristic rash and accompanying symptoms. The results of a complete blood count and clotting studies are normal.

Nonsteroidal antiinflammatory drugs are the traditional therapy for the arthralgias observed with HSP. Use of corticosteroids for the management of abdominal pain and renal involvement is controversial. Outpatient management is usually sufficient, although substantial joint or abdominal discomfort may require inpatient admission. Severe abdominal pain, especially in conjunction with guaiac test–positive or grossly bloody stools, merits an evaluation for intussusception.

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux (GER) is caused by a loose esophageal sphincter with retrograde passage of food into the esophagus. It is usually manifested in the first few weeks after birth as emesis during or soon after the cessation of feeding. The emesis may be blood streaked but should never be bilious. Some children in whom GER is eventually diagnosed may have previously been incorrectly labeled as having colic, feeding difficulties, or formula intolerance.

Symptoms of GER range from small “wet burps” to discomfort during feedings with arching of the back. One particularly severe form of reflux is the Sandifer syndrome, in which the child has opisthotonic movements and unusual head and neck positioning. The head movements may be an attempt to reduce pain by elongating the esophagus and protecting the airway from aspiration. Complications of GER include failure to thrive, apnea, laryngospasm, and aspiration pneumonia. Reflux esophagitis may be the culprit in children with guaiac test–positive stools or iron deficiency anemia. In most cases, GER resolves spontaneously by 1 year. The diagnosis is most often made from a careful history. Esophageal pH probe, nuclear milk scan, barium swallow study, and direct feeding under fluoroscopic observation are all diagnostic options.

Nonpharmacologic interventions are frequently sufficient to relieve the majority of cases of GER. Smaller-volume feedings with breaks for burping are often helpful. Caregivers should be instructed to keep children semiupright for 30 to 45 minutes after feedings. Thickening of feedings with cereal reduces crying and improves symptoms.

Ranitidine, a histamine blocker, reduces gastric acid and aids mucosal healing. Metoclopramide stimulates esophageal and gastric motility, thereby decreasing the volume of gastric contents that may reflux. GER that is severe and resistant to medical therapy may require surgical intervention with a Nissen fundoplication. This procedure involves wrapping and surgically fixing a portion of the stomach around the esophagus.

PYLORIC STENOSIS

Pyloric stenosis results from idiopathic hypertrophy of the antrum of the stomach. The male-to-female ratio is 5:1, and familial occurrence is present in up to 50% of patients. It is usually diagnosed in children at 2 to 5 weeks of age and rarely after 3 months. They feed normally at first but later experience vomiting in the midst of or soon after feeding. The emesis begins as mild and small and then progresses to voluminous and projectile. It is never bilious, although it may be blood streaked. The patient appears to vomit the entire bottle and then refeeds ravenously. After eating, peristaltic waves may be visible across the abdomen. If the condition continues, the child loses weight and becomes dehydrated, with sunken eyes, loose skin, and lethargy. Electrolyte analysis shows a hypochloremic, hypokalemic metabolic alkalosis. As the child continues to vomit, hydrogen and chloride are expelled. The kidneys attempt to maintain normal pH by eliminating potassium and hydrogen ions.

The differential diagnosis includes GER, overfeeding, and gastritis. Careful examination may detect the pylorus or “olive,” especially in a thin, dehydrated child with prolonged illness. Pyloric stenosis is identified with either ultrasonography or an upper GI series. Ultrasonography is the preferred modality because in addition to its high rate of accuracy, no radiation exposure is involved. Ultrasonographic diagnosis is made by visualization of a thickened pylorus. An upper GI radiographic series will demonstrate a “string sign” as the contrast agent squeezes through a narrowed pylorus.

Surgery is the treatment of choice for pyloric stenosis. However, diagnosis of this disorder does not represent a surgical emergency. ED management consists of rehydration and correction of electrolyte status before surgical intervention.

MALROTATION WITH VOLVULUS

Early in normal embryonic development, the intestine rotates around the superior mesenteric artery. The duodenum and cecum become widely displaced and fixed into position by peritoneal attachments called Ladd bands. They are loosely connected by a broad mesentery. In cases of malrotation, the cecum and duodenum do not separate but remain closely aligned. They are only loosely fixed into position, and the mesentery does not fan outward. This narrow stretch of mesentery, which contains the superior mesenteric artery, crosses over the duodenum. It can easily twist on itself and cause duodenal obstruction and arterial compression. The result is ischemia with the potential for intestinal necrosis within 1 to 2 hours.

The common manifestation is an acute onset of abdominal pain with bilious emesis. Abdominal distention may or may not be present, depending on the anatomic level of the obstruction. Affected children are usually seen in the first year of life, with the majority of cases occurring within the first week to month. Older children may have a history of intermittent episodes of vomiting and abdominal pain that suddenly become more severe. Bloody stools should raise the level of concern for bowel ischemia and impending gangrene. Patients are often quite ill and may be in shock at initial evaluation.

The differential diagnosis of bilious emesis in infants includes a short list of highly morbid conditions (Box 22.2).

In addition to malrotation, sepsis, small bowel obstruction, and necrotizing enterocolitis (NEC) must be considered.

A loop of small bowel overlying the liver may be visible on plain abdominal radiographs. Distal bowel gas is limited or absent. The “double bubble” sign can be visualized on an upright film; it is produced by a dilated stomach and duodenum. An upper GI radiographic series, the diagnostic study of choice, demonstrates abnormal anatomy with a coiled spring appearance of the jejunum in the right upper quadrant.8

All children with bilious emesis need immediate evaluation by a surgeon. Malrotation with midgut volvulus is a surgical emergency because bowel infarction can occur rapidly.

**NECROTIZING ENTEROCOLITIS**

NEC is generally a disease of premature infants and is usually diagnosed in the intensive care unit. However, up to 10% of infants with NEC are born at full term, so initial evaluation in the ED is a possibility. Signs and symptoms range from feeding intolerance and vomiting to pneumatosis intestinalis (air within the intestinal wall), perforation, shock, and disseminated intravascular coagulation. Most affected newborns experience vomiting, which may or may not be bilious. The clinical findings may be limited to guaiac test–positive stools and feeding intolerance, but in severe cases, infants have massively distended, rigid abdomens in the setting of shock. Gas within the biliary tract is present in 10% to 30% of cases. With improved survival of premature infants, children may be seen in the ED with sequelae of NEC, such as strictures, obstruction, fistulas, and short gut syndrome.

**APPENDICITIS**

Appendicitis is typically accompanied by diffuse or periumbilical abdominal pain. Within 8 to 24 hours, vomiting begins, and the pain migrates to the right lower quadrant. Abdominal pain, vomiting, and fever are the classic symptom triad for the disease. Although the pain precedes other symptoms in adult studies, such may not be the case in many children with appendicitis. Up to one third of pediatric cases do not follow this order of symptoms, and vomiting is often reported as the first sign. Fever is routinely low grade; a temperature higher than 39°C reduces the likelihood of appendicitis, except in cases of perforation.

The position of the appendix dramatically affects the location of the pain and symptoms. A normally placed appendix produces discomfort at the McBurney point. A low-lying pelvic appendix may irritate the sigmoid colon and mimic enteritis with diarrhea. A retrocecal appendix may produce flank or posterior pain and may be confused with pyelonephritis or septic arthritis of the hip.

Movement increases the discomfort (e.g., bumps in the car ride to the hospital, walking, jumping) such that patients may walk hunched over, limp, have a shuffling gait, or put weight preferentially on the left leg. Although anorexia is a classic finding, children can be enticed by their favorite foods and may even want to eat.

Examinations should be gentle, and the right lower quadrant should be palpated last to allow evaluation of reportedly nontender regions and to gain the patient’s confidence. Bowel sounds are usually normal or hypoactive. An external genital examination must be performed to exclude testicular disorders and incarcerated hernia.

Appendicitis is particularly difficult to identify early in the course of the illness and in the very young (Box 22.3).9 Approximately 90% of patients younger than 2 years with appendicitis have a perforated appendix at the time of diagnosis. Children have a thinner appendiceal wall and a less well-developed omentum. Therefore, rupture occurs more readily and results in more diffuse bacterial dissemination. Pediatric cases of appendiceal perforation have more severe and diffuse peritonitis than do adult cases. Although the mortality from appendicitis has improved dramatically, the rate of perforation has not changed significantly in the past few decades.

A complete blood count showing leukocytosis and a left shift is supportive of the diagnosis, but many children have normal white blood cell (WBC) counts.10 Most patients with appendicitis have an elevated WBC count in the range of 11,000 to 15,000 cells/mm³. An appendix in close proximity to the ureter can produce sterile pyuria and mild hematuria. A positive urine Gram stain response and the presence of leukocyte esterase and nitrites can help differentiate a true urinary tract infection from inflammatory hematuria secondary to appendicitis.

In the case of perforation, the pain initially resolves but then becomes more generalized with peritoneal symptoms. It may be most severe in both lower quadrants as the purulent material settles. Young children may simply have nonspecific...
symptoms such as fussiness, inconsolable crying, irritability, and grunting respirations. Once perforation occurs, the child may have poor perfusion, tachycardia, high fever (>39°C), and even septic shock. Bowel sounds are then absent; the abdomen is rigid with rebound tenderness and involuntary guarding. The WBC count is dramatically elevated with a significant left shift. A fecalith is visible on plain abdominal radiographs in 8% to 10% of patients with appendicitis. A number of other findings can be seen on plain films, including scoliosis concave toward the right side, a sentinel loop overlying the appendix indicating an area of inflammation, air within the appendix, a mass in the right lower quadrant (more often in cases of abscesses), and loss of the psoas shadow on the right.

Ultrasonography is a useful tool for evaluating children with concerns for appendicitis. The classic finding known as the “target sign” is a fecalith inside a large, inflamed appendix. In obese children, visualization and diagnosis become more challenging. The sensitivity and specificity of ultrasonography exceed 90%, but ruptured appendices are notoriously difficult to identify. No diagnosis can be made if the appendix is not visualized. Ultrasonography is helpful in differentiating appendicitis from other causes of abdominal pain, such as ovarian cysts, but cannot exclude conditions such as mesenteric adenitis. CT has a sensitivity and specificity higher than 95% and may be used in cases with a broad differential diagnosis or when the findings on ultrasound are equivocal or it is unavailable. Abdominal CT is helpful in diagnosing inflammatory bowel disease and mesenteric adenitis. Admission for serial abdominal examinations is warranted for a child with a compelling history and physical examination findings but equivocal laboratory findings.

A surgeon should be involved early in the ED evaluation of a child with suspected appendicitis because imaging may be avoided in classic cases. Pain must be addressed, and numerous studies have shown that narcotics do not affect the diagnostic accuracy of the examination. Surgeons may choose to evaluate the patient before analgesia is given, but pain medication should not be withheld indefinitely pending surgical assessment. Signs of shock should be addressed aggressively, and children with suspected rupture should receive broad-spectrum antibiotic coverage.

**HIRSCHSPRUNG DISEASE**

Hirschsprung disease is caused by the absence of ganglion cells in the myenteric plexus of the colon. Without ganglion cells, that segment is under constant contraction. The proximal region dilates to compensate, with resultant constipation. Patients have complaints of chronic constipation, abdominal distention, and vomiting. Physical examination demonstrates palpable stool in the abdomen with a tight anal sphincter, but absence of stool in the rectal vault. Hirschsprung disease has a 4:1 male preponderance. In 80% of affected patients it is diagnosed within the first year of life. The most serious complications are toxic megacolon, perforation, and enterocolitis. A dilated colon, fecal impaction, and air-fluid levels are visible on abdominal radiographs. The diagnosis is made from the finding of aganglionosis on biopsy or anal manometry. A barium enema without bowel preparation shows a narrowed colonic segment and a dramatically dilated proximal segment. In uncomplicated cases, outpatient surgical evaluation is indicated. Resection of the aganglionic segment is curative.

The vast majority of cases of constipation are functional and tied to behavioral and psychologic causes. Pathologic causes are rare and, in addition to Hirschsprung disease, include cystic fibrosis and hypothyroidism.

**BILIARY TRACT DISEASE**

Gallstones are an unusual condition in healthy children. The most common type, pigment stones, usually develop in children with underlying hemolytic conditions such as sickle cell disease and hereditary spherocytosis. Cholesterol stones are more prevalent in adolescent girls, obese children, patients with cystic fibrosis, and those who depend on total parenteral nutrition. Because of the large percentage of pigment stones, up to 50% of cases of cholelithiasis in children are visible on abdominal radiographs, in contrast to 10% to 15% of cases in adults.

Acalculous cholecystitis (inflammation of the gallbladder in the absence of gallstones) is more common in children than cholelithiasis is. Causes include Kawasaki disease; bacterial infections such as typhoid, shigellosis, and scarlet fever; and viral infections such as hepatitis.

Acute cholangitis usually occurs in children with a history of biliary surgery, as used for the management of choledochal cysts and biliary atresia. The clinical picture is similar to that in adults and consists of right upper quadrant pain, fever, and vomiting. Treatment is inpatient admission for therapy with broad-spectrum antibiotics such as ampicillin, gentamicin, and metronidazole.

**MILK PROTEIN ALLERGY**

Milk protein allergy is manifested as blood-streaked, mucous stools in young infants exposed to cow’s milk–based formulas. Significant flatus and mild discomfort with feeding may be noted. However, most children appear nontoxic and otherwise well. Edema, inflammation, and discrete ulcerations are present in the intestinal mucosa. This condition is best described to occur with consumption of milk protein but may develop with any formula, including soy. Treatment is to change to a formula with a different protein source. The symptoms should resolve within 1 week of complete withdrawal of the offending agent.

REFERENCES

better than that of an adult, so a child’s blood pressure may be maintained despite large volume loss. Once a critical percentage of blood volume is lost (25%), a child’s blood pressure can drop precipitously, partly because of the inability of pediatric patients to change cardiac contractility and their dependence on the compensatory mechanisms of increased peripheral vascular resistance and heart rate. It should be noted that posttraumatic pediatric hypotension may also be an indicator of head injury rather than hemorrhage.3

**APPRAOCH AND MANAGEMENT**

The ABCs of resuscitation (airway, breathing, circulation) should first be used to identify the loss of an airway or respiratory failure (or both). Direct injuries to the airway (oropharynx, trachea, or bronchi) are not the only cause of airway failure. An expanding neck hematoma or aspirated foreign body can have similar effects.

Breathing difficulty in children may be the sequelae of insults to the chest wall, lungs, heart, great vessels, or abdomen, as well as neurologic or muscular injuries. It may also result from the loss of ventilatory musculature, as with a cervical spine injury or respiratory muscle fatigue. Young children may have disordered ventilation secondary to gastric distention because considerable air is gulped into the stomach during crying.4

Circulation can be assessed in children through an evaluation of mental status, skin color and temperature, heart sounds, pulses, and capillary refill. Shock should be identified and treated immediately. Children differ from adults in several critical ways. The leading cause of cardiac arrest in children is hypoxemia. Normal blood pressure may be maintained in children sustaining trauma despite severe injury and massive blood loss (up to 25%). Shock in the setting of trauma should be presumed to be secondary to blood loss and be treated by restoration of volume. Two intravenous (or intraosseous) lines of the largest bore possible should be established immediately. Two boluses of crystalloid solution, 20 mL/kg each, should be administered. If shock persists, packed red blood cells should be transfused at 10 mL/kg and repeated as necessary. Other causes of shock, such as tension pneumothorax, pericardial tamponade, neurogenic shock, hypoxemia, metabolic derangements, and toxidromes, should be sought and treated concomitantly with restoration of volume.
Disability must be assessed thoroughly. Mental status is evaluated with the Glasgow Coma Scale (GCS) or an AVPU (alert, verbal, painful, unresponsive) scale (Table 23.1). An age-appropriate examination should be performed to evaluate for neurologic deficits.

Exposure of the body immediately after the ABCs have been addressed is imperative in all pediatric trauma patients. Emergency personnel should briefly expose and roll (with precautions) the patient to assess for initially unapparent injuries, such as a puncture wound in the posterior aspect of the chest in a victim of assault. Because of the increased ratio of surface area to volume in children and a propensity for hypothermia, blankets and warmed intravenous fluids should be used to maintain normothermia. Whenever feasible, family presence, which has been shown to not impede pediatric trauma resuscitation, should be accommodated during resuscitation to comfort the child. The emergency practitioner should communicate with the child during the examination.

After exposure, the secondary survey should be performed. An AMPLE history (allergies, medications, past medical history, last meal, and events leading up to the patient’s arrival in the ED) is obtained, followed by a complete head-to-toe examination. Particular attention should be paid to the eyes, ears, mouth, axillae, hands, and genitals. The utility of rectal examination has recently been called into question. In particular settings where questionable neurologic deficits are present or rectal or urogenital trauma is evident, a rectal examination may prove useful. It should be selective to avoid unnecessary emotional stress in the child. In an unconscious intubated patient, an orogastric or nasogastric tube and Foley catheter should be placed. As part of the secondary survey, initial radiographs and laboratory studies should be selectively ordered to further investigate any history and physical findings.

Younger children, particularly infants, have little functional ventilatory reserve. Time is therefore of the essence in restoring oxygenation, ventilation, and circulation. The ABCs of resuscitation should be repeated if there is any change in the patient’s status.

The most common life- and limb-threatening injuries in children are those to the head, chest, and abdomen. In each of these areas, there are subtle but important clues to such injuries (Box 23.1).

immediate bedside glucose test, a complete blood count, serum chemistry analysis, coagulation studies, urinalysis, blood typing and cross-matching, blood gas measurements, and a pregnancy test. Further radiologic testing (e.g., computed tomography [CT], angiography, magnetic resonance imaging [MRI]), as well as more in-depth laboratory testing (e.g., hepatic function tests, screening for toxins or drugs, pancreatic enzyme measurements), may be ordered as indicated.

There are some pediatric-specific issues in the management of trauma. With younger patients, small tubes should be used for laboratory testing to avoid iatrogenic blood loss. The clinician should be aware that the hematocrit does not drop immediately in a child with acute blood loss before receiving isotonic volume resuscitation. For minimally injured patients, such as those with isolated extremity fractures or low-risk head or abdominal trauma, no laboratory studies are needed. In patients requiring an observation period, tracking the hematocrit or hemoglobin may be useful in combination with clinical reassessment. Toxidromes must be considered, especially in a patient with altered mental status, if the circumstances of the event are suspicious or when the patient is a teenager.

The ALARA (as low as reasonably achievable) principle should be applied to minimize exposure to radiation. The clinician should limit the number of CT scans performed and should make size-based adjustments to the radiation scanning parameters. Some investigators have questioned the need for portable radiographs of the cervical spine, chest, and pelvis to screen for injury in all trauma patients. As with trauma triage, it is advisable to err on the side of caution. These studies should be performed in all seriously injured patients or if the status of the spine, chest, or pelvis is at all uncertain. A more focal radiologic screening examination, as indicated by the history and findings on physical examination, may be considered in stable patients with normal mental status. Children younger than 2 years in whom child abuse is suspected must undergo a skeletal radiographic survey to diagnose occult or remote injuries.

**PEDIATRIC HEAD TRAUMA**

**KEY POINTS**

- Head trauma is responsible for 80% of pediatric trauma deaths.
- Cervical immobilization is required if head injury is suspected.
- The AVPU scale can be used in children as an alternative to the GCS score.
- Significant alterations in a child’s mental status should prompt early airway management and immediate CT of the brain.
- Declining mental status with suspected intracranial injury requires immediate neurosurgical evaluation or transfer of the patient to a facility with neurosurgical capability.

**DOCUMENTATION**

The following information should be documented:

- **History**
  - Prehospital history
  - Detailed mechanism of the injury (e.g., speed of the vehicle, height of the fall)
  - Circumstances of the injury (e.g., damage to the vehicle, type of weapon)
  - Timing of the event
  - Time until arrival at the emergency department
  - Concurrent medications
  - Patient’s access to medications or exposure to drugs or toxins
  - Past medical history
  - Last meal
  - Immunizations
  - Previous surgeries
  - Inconsistencies in the history between witnesses, particularly when child abuse is suspected

- **Physical Examination**
  - Primary survey and interventions
  - Head-to-toe physical examination

- **Laboratory Studies**
  - Emergency department interpretation of radiographs
  - Laboratory studies ordered and their results
  - Results of focused abdominal sonography for trauma or diagnostic peritoneal lavage

- **Medical Decision Making**
  - Reasons to pursue or not pursue a work-up for each injury
  - Timing of consultation of surgical or other subspecialists

- **Procedures**
  - Each procedure in full

- **Patient Instructions**
  - Discussion of injuries and potential outcomes with the patient, patient’s family, or both

**SCOPE AND OUTLINE**

Head injury is the leading cause of death and is responsible for 80% of pediatric trauma deaths. Annually in the United States, 500,000 emergency department (ED) visits and almost 100,000 hospital admissions are due to pediatric head trauma. The leading causes of head trauma are falls, motor vehicle collisions, bicycle accidents, auto-pedestrian accidents, diving injuries, sporting accidents, and child abuse.

**PATHOPHYSIOLOGY**

Children have relatively larger heads than adults do. A child’s skull is thinner and less rigid than an adult’s, and infants and younger children have open or soft sutures, which can help decompress elevations in intracranial pressure. As a result, parenchymal injury may occur in the absence of a skull fracture.
CLINICAL PRESENTATION

Major intracranial injuries may be immediately apparent from the patient’s depressed level of consciousness or confusion or from abnormal neurologic findings. Significant injuries may be present in a patient with completely normal neurologic findings. Early recognition and treatment of mild or moderately severe head injury in a child are as important as recognition and treatment of serious injuries (see Red Flags: Warning Signs box). An epidural hematoma in a mildly confused victim of a car accident can have dire consequences. It is important to screen for injuries to other systems and to aggressively treat a child with a head injury. Strict attention should be paid to maintaining oxygenation and cerebral perfusion in a head-injured child to avoid secondary injury.

RED FLAGS

Warning Signs of Intracranial Injury in Children with Head Trauma
- Prolonged loss of consciousness
- Multiple seizures
- Persistent vomiting
- Amnesia
- Lethargy
- Irritability
- Large cephalohematoma or clinical skull fracture
- Abnormal neurologic findings

APPROACH AND MANAGEMENT

A physical examination should be performed with attention to any neurologic findings. Obvious external head and neck trauma may be an indicator of serious injury, although severe internal injury often exists with minimal or no external signs. The GCS or AVPU scale may be used to assess mental status. An age-appropriate neurologic examination may reveal deficits requiring further testing and treatment. The clinician should have a low threshold for managing the airway of a pediatric trauma patient with altered mentation.

DIAGNOSTIC TESTING

The goal of diagnostic testing in children in whom intracranial injury is suspected is to identify those with injuries that will require intervention before the condition worsens. A secondary goal is to avoid unnecessary testing and admission, both to prevent overutilization of resources and to avoid unnecessary exposure to radiation. The most commonly used and most widely available options for the evaluation of children with head injuries are plain radiography of the skull, CT of the head, and observation with serial examinations.

CERVICAL SPINE INJURY

SCOPE AND OUTLINE

Spinal cord injuries are uncommon in children and account for less than 2% of injuries found in pediatric trauma patients. Motor vehicle collisions represent the most common mechanism for this injury, and death is usually secondary to brain injury.

PATHOPHYSIOLOGY AND ANATOMY

Mechanisms of fractures of the cervical spine in children are similar to those in adults, although children have a higher risk for ligamentous injuries. Because the pediatric cervical spine is hypermobile, a traumatic injury can cause transient severe ligamentous disruption and lead to brief sensory or motor deficits or electric shocks with rapidly clearing weakness. The initial rapid resolution of symptoms represents realignment of structures with the counterforce of the injury such that the cord is drawn back into its anatomic position. Unfortunately, this phase can be followed by delayed neurologic deficits precipitated by cord edema after this stretch injury. The delay can be quite significant, with deficits appearing up to 4 days after the inciting event.

Fortunately, documented cases of this type of injury, known as spinal cord injury without radiographic abnormality (SCIWORA), tend to not be subtle in a preverbal child and result from impressive multiple-trauma mechanisms such as falls from extreme heights and motor vehicle accidents involving a high-risk mechanism. In a verbal older child, SCIWORA can initially be manifested as mild transient neurologic deficits requiring further testing and treatment.

Incomplete ossification of the posterior elements
Physiologic C1-C2 widening
Predental space should not exceed 5 mm in children (3 mm in adults)
Pseudosubluxation at C2-C3 and C3-C4 (see Fig. 23.1)
Hypermobility or ligamentous laxity of the intervertebral ligaments
Horizontal orientation of the facet joints, which allows increased mobility and leads to:
- Loss of normal lordosis
- Pseudosubluxation of C2 on C3
- Spinal cord injury without radiographic abnormalities
Accentuated prevertebral soft tissue spaces, which should not exceed two thirds of the C2 body
Portions of the vertebrae are radiolucent or wedge-shaped up to 8 years, which leads to widened disk spaces and anterior wedging
Anatomic fulcrum in children younger than 8 years between C1 and C3:
- Most injuries occur in the upper cervical spine
- After age 8, the anatomic fulcrum is between C5 and C6
Fig. 23.1 Radiographs showing pseudosubluxation of the cervical spine. The clinician should draw a line through the cortices of the spinous processes of C1 and C3. If the cortex of the spinous process of C2 is more than 1.5 mm off this line (line of Swischuk), a fracture or ligamentous injury should be suspected. A, Normal cervical spine with pseudosubluxation. Note that the line of Swischuk is straight but the anterior and posterior spinal lines have step-offs. B, The cortex of the spinal process of C2 is less than 1.5 mm off the line of Swischuk.

complaints. Heightened awareness of this phenomenon is needed so that the treating physician can take the necessary steps for diagnosis and treatment.

DIAGNOSTIC TESTING

PLAIN RADIOGRAPHS
The two studies most widely used to predict cervical spine injury, the Canadian C-Spine Study and the National Emergency X-Radiography Utilization Study, did not target the pediatric population. Though still requiring prospective validation, the Pediatric Emergency Care Applied Research Network (PECARN) recently published an eight-variable model for predicting pediatric cervical spine injury: altered mental status, focal neurologic findings, neck pain, torticollis, substantial torso injury, congenital conditions predisposing to cervical spine injury, diving, and high-risk motor vehicle crash. The presence of one or more of these factors was 98% sensitive and 26% specific for cervical spine injury (Boxes 23.3 and 23.4).

Flexion and extension radiographs of the cervical spine are not used in the acute management phase of children in the ED.

COMPUTED TOMOGRAPHY
Evidence is mounting that patients with a high-risk mechanism of injury, such as a fall from a height or a high-speed motor vehicle collision, should undergo CT evaluation of the cervical spine.

MAGNETIC RESONANCE IMAGING
To exclude the possibility of SCIWORA, any history of transient neurologic dysfunction requires extended observation or MRI, even if findings on plain radiography are normal.
CHAPTER 23  PEDIATRIC TRAUMA

TREATMENT AND DISPOSITION
Immobilization with a cervical collar is required for any child with a cervical injury. When such an injury is diagnosed, emergency consultation with a pediatric spine surgeon and admission of the patient to the hospital are mandatory. Though still somewhat controversial, there is no evidence to recommend the use of high-dose methylprednisolone in the treatment of pediatric spinal cord lesions with neurologic deficits after blunt trauma.9

PEDIATRIC THORACIC TRAUMA

KEY POINTS
- Respiratory distress or hypoxemia should prompt a thorough radiographic evaluation.
- Gastric decompression should be performed early in any child with respiratory distress or hypoxemia.

PERSPECTIVE
Trauma involving the chest is the second leading cause of death from trauma in children. The majority of cases are the result of blunt mechanisms. Associated injury is the most important mortality factor. The death rate from isolated chest trauma in children is 5%, whereas that from abdominal and chest trauma is 20% and that from trauma involving the head, chest, and abdomen is 39%.11

ANATOMY AND PATHOPHYSIOLOGY
The thorax of a child is smaller and more compliant than that of an adult. Because children’s bones are less dense and less rigid, less force is required for intrathoracic injury. Associated abdominal, pelvic, and head injuries are relatively common, and the clinician should suspect concomitant abdominal injuries in victims of chest trauma until proved otherwise. Infants and toddlers depend on diaphragmatic breathing, and therefore respiratory depression can develop if mobility of the diaphragm is impaired. In children, the ratio of oxygen consumption to mass is high and functional residual capacity is lower, thereby putting them at risk for sudden respiratory failure and rapid oxygen desaturations with little to no warning.

CLINICAL PRESENTATION
Patients with major thoracic injuries frequently have significant chest pain, respiratory distress, disordered chest and abdominal movement, hypoxemia, or hemodynamic compromise. They may also exhibit chest deformity, flail chest, crepitus, decreased breath sounds, or sucking chest wounds.

BOX 23.5 Most Common and Most Lethal Injuries Involving the Chest in Children

Most Common
- Pulmonary contusion
- Rib fractures
- Pneumothorax
- Hemothorax
- Cardiac injury
- Great-vessel injury
- Diaphragmatic injury

Most Lethal
- Great-vessel injury
- Cardiac injury
- Hemothorax
- Rib fracture

BOX 23.6 Indications for Computed Tomography of Chest in Pediatric Trauma

- Wide mediastinum on a chest radiograph
- Thoracic spine fracture
- Superior rib fracture
- Abnormal lung fields
- Unexplained hypotension or hypoxemia
- New cardiac murmur or carotid bruit
- Asymmetric pulses or blood pressure

Thoracic injuries account for 5% to 12% of admissions to pediatric trauma centers,12 but many children evaluated for chest trauma in the ED have much more subtle findings (Box 23.5). Children with chest pain, dyspnea, altered mental status, tachypnea, retractions, hypoxemia, shock, multiple-system trauma, or concern because of a high-risk mechanism should be evaluated for thoracic trauma. Injuries may occur in isolation or in combination with other thoracic or extrathoracic problems. Significant injuries may be present with little or no external evidence.

DIAGNOSTIC TESTING
CHEST RADIOGRAPHY
A chest radiograph is the most useful test in the evaluation of suspected chest trauma, although it is not as sensitive as CT scanning for many diagnoses, such as rib fracture, sternal fracture, pneumothorax, hemothorax, pulmonary contusion, and great-vessel injury. A chest radiograph should be obtained to confirm endotracheal position, identify intrathoracic causes of hypotension, exclude pneumothorax in patients with suggestive signs or symptoms (e.g., respiratory distress, crepitus, tenderness), or evaluate for external evidence of thoracic trauma.13

COMPUTED TOMOGRAPHY OF THE CHEST
The best test to define the extent of intrathoracic injury is CT. For evaluation of great-vessel injury, CT angiography has largely replaced angiography (Box 23.6).
**SPECIFIC INJURIES**

**RIB FRACTURES**
Rib fractures are less common in children than in adults. The compliance of a child’s rib cage allows transfer of strong force to the internal organs before fracture. Half of significant intrathoracic injuries in children occur without a rib fracture. Mortality rises with the number of fractures. Rib fracture, particularly posterior and multiple ones in a young infant, should raise suspicion for nonaccidental trauma. Flail rib segments, or three or more ribs broken in a segmental fashion, can lead to serious respiratory compromise. The clinician should manage pain aggressively, and early intubation should be considered in a child with flail chest or multiple rib fractures. Otherwise, treatment is supportive. In addition to parietal pain medication, intercostal nerve block and epidural anesthesia can be effective.

**PULMONARY CONTUSION**
Pulmonary contusion occurs in up to 71% of children with thoracic injuries. Because of the increased compliance of the rib cage in children, force is transferred directly to the lung parenchyma. Parenchymal hemorrhage and edema lead to alveolar collapse and disorders of gas exchange. Contusions large enough to impair respiratory function may occur without any external signs of trauma. Contusions may be immediately visible on chest radiographs or have a delayed appearance. The radiographic appearance of a pulmonary contusion ranges from minimal hazy opacity to a diffuse, dense infiltrate. The sensitivity of chest radiography for detection of pulmonary contusion was 67% in one study that used CT of the chest as the “gold standard.” Contusions not visible on chest radiographs were not clinically significant and did not require a change in management. Treatment of pulmonary contusion consists of pain control, pulmonary toilet, and mechanical ventilation when appropriate.

**PNEUMOTHORAX**
Though spontaneous at times, pneumothorax occurs primarily in children as a result of trauma. Signs and symptoms are pain, dyspnea, hemoptysis, tachypnea, retractions, hypoxemia, decreased breath sounds, and tachypnea. The clinician should also consider pneumothorax in the setting of chest wall abrasion, contusion, laceration, wound, or deformity. Auscultatory lung examination is unreliable because the small chest cavity in children transmits breath sounds easily even in the presence of pneumothorax. Because of the mobile pediatric mediastinum, tension pneumothorax can result in rapid cardiovascular and ventilatory collapse.

The primary screening examination is a chest radiograph, performed with the patient supine if the cervical spine has not been determined to be uninjured. It is an insensitive test for pneumothorax, with some estimates of sensitivity as low as 20% to 60%. An upright chest radiograph should be performed if possible. CT of the chest is extremely sensitive for the detection of pneumothorax, even very small ones that may need no intervention. Abdominal CT may demonstrate pneumothorax, but patients with pneumothorax detected only by this modality uncommonly need tube thoracostomy (Table 23.2). In adults, bedside ultrasonography has been shown to be comparable in specificity but more sensitive than chest radiography for the detection of traumatic pneumothorax.

**DIAPHRAGMATIC INJURY**
Injury to the diaphragm may result from either penetrating trauma or, more commonly, a major blunt injury to the abdomen, such as a fall from a height, a crush injury, or a high-speed motor vehicle collision. Diaphragmatic injury is uncommon in children and occurs in about 3% of victims of blunt abdominal trauma. Patients may be asymptomatic, may have chest or abdominal pain, or may initially be seen with respiratory failure and shock.

The diagnosis of diaphragmatic injury is difficult. If significant abdominal contents have herniated into the thorax, the diaphragmatic injury may be diagnosed on screening chest radiography. Overall, sensitivity rates for both chest radiography and chest CT are not good. Sensitivity rates for CT of the chest in detecting blunt diaphragmatic rupture have been reported to be 42% to 90%. One study found that diaphragmatic injury was correctly diagnosed on admission in only 50% of patients admitted to a level I trauma center. Diagnostic peritoneal lavage (DPL) may have some utility in detecting diaphragmatic injury, although it is performed less frequently today than previously. Its sensitivity has been reported to be 80% in a selected population, although it is not specific. Because of the pressure differential between the abdomen and thorax, any missed defect in the diaphragm will continue to enlarge until it is repaired surgically.

**CARDIAC CONTUSION**
A patient with a cardiac contusion may complain of chest pain or palpitations. External findings are sternal fracture, rib fracture, chest contusion, and sometimes no signs of trauma. The most common dysrhythmia is sinus tachycardia. The patient is unlikely to have complications if the findings on electrocardiography (ECG) are normal and the troponin level is normal over a 6- to 12-hour period of observation. In one study of pediatric blunt cardiac injury, no hemodynamically stable patient with a normal sinus rhythm subsequently demonstrated a cardiac arrhythmia or cardiac failure. Use of any changes on ECG, including sinus tachycardia, bradycardia, conduction delays, and atrial or ventricular dysrhythmias, can provide a sensitivity of 100%, a specificity of 47%, and a negative predictive value of 90% for the detection of complications related to blunt cardiac injury that require treatment.

</tr>
</tbody>
</table>

Several prospective series have demonstrated that if admission ECG displays normal sinus rhythm, the risk for development of cardiac complications related to blunt cardiac injury is extremely small.20,21

COMMOTIO CORDIS
Commotio cordis resulting from blunt chest trauma that caused cardiac arrest has been reported to occur in children. The clinician should apply the normal pediatric advanced life support algorithm for treatment. Commotio cordis may or may not respond to treatment.

TRAUMATIC ASPHYXIA
Traumatic asphyxia is unique to children. Findings include cervical and facial petechiae or cyanosis with vascular engorgement and subconjunctival hemorrhage. The syndrome is secondary to blunt, compressing thoracic trauma with airway obstruction and retrograde high pressure in the superior vena cava. Central nervous system injuries, pulmonary contusions, and intraabdominal injuries are commonly associated with thoracic injuries. Despite the dramatic manifestation of traumatic asphyxia, the overall prognosis is good for patients who arrive at the ED with normal vital signs.

DISPOSITION
Children with significant thoracic trauma are admitted to the hospital after the trauma surgery team has been consulted. In centers where pediatric trauma care is unavailable, transfer to a pediatric trauma center is recommended. A child with an isolated rib fracture and a small pneumothorax who is stable on chest radiography after 4 to 6 hours of observation or in whom a suspected myocardial contusion has been ruled out may be discharged. Any child with suspected child abuse whom a suspected myocardial contusion has been ruled out should receive a thorough evaluation and be considered for hospital social workers should be contacted to investigate, and hospital social workers should be involved.

PEDIATRIC ABDOMINAL TRAUMA

KEY POINTS
- Abdominal trauma is the third leading cause of traumatic death in children.
- Most intraabdominal injuries are the result of blunt trauma.
- Missed intraabdominal injuries are a leading cause of preventable death.
- Children in whom intraabdominal injury is suspected are admitted to a pediatric trauma center.
- Most injuries to solid organs are managed nonoperatively.

PERSPECTIVE
Motor vehicle accidents are the leading cause of abdominal trauma, although falls, sports accidents, and child abuse account for a significant number of injuries. Children struck by motor vehicles or who as motor vehicle passengers are not properly restrained or are ejected are at increased risk. Blunt trauma accounts for 90% of all pediatric injuries.22 Missed intraabdominal injury in the setting of blunt abdominal trauma is a leading cause of preventable mortality and morbidity in children.

ANATOMY AND PATHOPHYSIOLOGY
The abdomen of a child is smaller than that of an adult, so forces are distributed over a smaller area. Children have less adipose tissue than adults do, and the muscular layers of the child’s abdomen are thinner and weaker. External forces are transmitted efficiently to abdominal organs. In children found to have intraabdominal injuries, multiple-organ injury is common. Injuries to solid organs, such as the liver, spleen, pancreas, and kidneys, may result in significant hemorrhage. Hollow viscus injuries rarely result in hemodynamic compromise and are more challenging to diagnose in the ED. Injury to the inferior ribs, lumbar spine, or pelvis should raise suspicion for intraabdominal injury.

CLINICAL PRESENTATION
Children with abdominal injuries may exhibit abdominal pain, vomiting, distention, or abdominal tenderness; however, they may also have none of these findings. Intraabdominal injuries should be strongly suspected in children with altered mental status, hemodynamic instability, respiratory distress, or injury to multiple systems. Head injuries, fractures, and even significant soft tissue injuries should be considered distracting injuries in children. A thorough abdominal evaluation should be performed in children suspected of sustaining abdominal trauma. It is important to remember that significant intraabdominal injury can occur in children without any external evidence of trauma. An example is a child who sustains a handlebar injury to the abdomen at normal bicycling speed. Such a child may have a completely transected pancreas and torn duodenum and yet have no external signs of trauma.

Abdominal trauma in children is a challenge to evaluate and manage, even in the setting of hard evidence of intraabdominal injury (e.g., positive FAST findings). Most children with blunt trauma do not have intraabdominal injury, and most of those with solid organ injury do not require surgery. Serious injuries commonly occur in the setting of high-risk mechanisms, but they also occur in what may initially be reported as minor trauma. Identification of injuries in preverbal children or those who do not have normal mental status is difficult. A high index of suspicion is required, even in a stable patient. The clinician should pay particular attention to injuries from an automobile lap belt or bicycle handlebar.

In a patient with free fluid in the abdomen, the physician should start with a bolus of crystalloid solution. If the patient is stabilized and does not have other threats to life or limb,
CT of the abdomen and pelvis should be performed immediately to identify and grade the injury.

**DIAGNOSTIC TESTING**

**LABORATORY VALUES**

Routinely ordering a full “trauma panel” of laboratory tests is not recommended for a child with abdominal trauma. In a hypotensive patient, blood typing plus cross-matching is the most important laboratory test to order early. In patients with a low risk for intraabdominal injury, urinalysis may be the only test with relatively high diagnostic yield. Few consistent data are available to support a recommendation for which laboratory tests to order for screening of children with low- to moderate-risk trauma for the presence of intraabdominal injury. In children with blunt abdominal trauma, Holmes et al. recently validated a six-variable prediction rule (94% sensitive and 37% specific) for identifying intraabdominal injuries: low age-adjusted systolic blood pressure, abdominal tenderness, elevated hepatic enzymes (aspartate transaminase > 200 U/L or alanine transaminase > 125 U/L), urinalysis with more than five red blood cells per high-power field, initial hematocrit lower than 30%, and the presence of a femoral fracture.

**FOCUSED ABDOMINAL ULTRASONOGRAPHY FOR TRAUMA**

The sensitivity of FAST in pediatric trauma is 55% to 82%. Its utility is higher in unstable patients. The finding of free fluid on FAST in stable pediatric patients rarely leads to operative management. The vast majority of children with such findings are observed and discharged with some restrictions in activity and appropriate return precautions. For this reason, an argument can be made that abdominal ultrasonography is less useful in pediatric trauma. One study found that using ultrasonography as a triage tool can reduce the cost of pediatric abdominal evaluation. Ultrasound allows the clinician to quickly identify significant intraperitoneal fluid that would require further evaluation and possible laparotomy. In this study, children with positive ultrasonographic findings who showed a response to initial fluid resuscitation underwent abdominal CT, and unstable patients underwent laparotomy. This approach allowed a major reduction in the number of CT scans performed. It has also been suggested but not proved that FAST, aside from being a screening tool, is sufficient for evaluation of the majority of children sustaining blunt abdominal trauma.

**COMPUTED TOMOGRAPHY**

Abdominal CT should be performed in any stable patient in whom intraabdominal injury is suspected or to type and grade the injury in a patient with a positive FAST finding. Intravenous administration of a contrast agent is sufficient, and oral administration is not necessary (Box 23.7). CT findings allow the inpatient trauma service to select the appropriate level of inpatient care and monitoring for the patient. Although CT is excellent for evaluating solid organ injury, it is less sensitive for mesenteric, intestinal, and diaphragmatic injuries. If these latter injuries are suspected, further evaluation, such as admission to the hospital, serial abdominal examinations, and laboratory tests, are indicated. There are drawbacks to the routine performance of CT in any child in whom intraabdominal injury is suspected after trauma. CT is expensive, requires transport away from the direct caregiving environment, and may necessitate sedation of the child. In addition, computed risk estimates now suggest that CT may impose a higher lifetime risk for radiation-induced cancer in children than in adults. Use of the six-variable prediction rule by Holmes et al. (described earlier) has the potential to reduce unnecessary CT examinations by 30%.

**DIAGNOSTIC PERITONEAL LAVAGE**

Although it has fallen out of favor with the increasing availability of CT and ultrasonography, DPL still plays a role in the management of abdominal trauma. This procedure has excellent sensitivity for intraabdominal injury and may be of value in unstable pediatric trauma patients with suspected intraabdominal injury. DPL is also useful in the evaluation of children with penetrating injury to the abdomen, particularly in stable patients in whom a bowel injury is suspected that would not be well evaluated with either FAST or CT of the abdomen.

**SPECIFIC INJURIES**

Penetrating injuries to the abdomen must be evaluated by a surgeon. If the wound is suspected of violating the abdominal fascia, surgical exploration is the standard of care. Blunt injuries to the abdomen may cause a variety of internal damage, and a high index of suspicion is therefore required in their evaluation.

The seat belt sign refers to ecchymoses, abrasions, or erythema caused by restraint by the seat belt across the abdomen during a motor vehicle accident. Its presence carries an increased risk for intraabdominal injuries, particularly to the intestines and pancreas. Proper, age-appropriate restraint of a child in an automobile is extremely important. Proper seat belt use does not increase the risk for injury, but use of just a lap belt does change the spectrum of injury. Other injuries associated with the use of lap belts are facial fractures and lumbar spine fractures termed Chance fractures.

**Box 23.7 Indications for Computed Tomography of the Abdomen in Pediatric Trauma**

- Abdominal pain
- Distracting injury accompanied by suspicion of abdominal trauma
- Altered mental status
- Hemodynamic instability without an identifiable source
- Abdominal tenderness
- Seat belt sign
- Inferior rib fractures
- Thoracolumbar spine fractures
- Pelvic fractures
- Gross hematuria
Solid organ injuries include injuries to the liver, spleen, kidneys, and pancreas. Findings on FAST may or may not be positive in the presence of a solid organ injury. Injuries that are the result of blunt trauma are increasingly being managed nonoperatively in stable patients. In unstable patients, resuscitation with crystalloid solution followed by the administration of blood is attempted. If the patient’s condition stabilizes, nonoperative management may still be appropriate, as determined by the pediatric trauma surgeon who has seen and evaluated the patient. Unstable patients in whom FAST demonstrates free fluid in the abdomen go directly to surgery. Even if nonoperative management is the plan, admission to a pediatric trauma center, usually to an intensive care unit for at least the first 24 hours, is required.

Hollow viscus injury may occur with penetrating or blunt trauma. In penetrating trauma, enterotomy may occur when a missile or sharp object passes directly through the intestine. In blunt trauma, a portion of a viscus, such as the sigmoid or the duodenum, may be crushed against the retroperitoneum and could rupture. A portion of a viscus may rupture from sudden increases in intraabdominal pressure or may be torn by being swung forcefully on the mesentery with a sudden deceleration.

Mesenteric injuries may also occur with similar mechanisms. FAST findings are frequently normal in the setting of hollow viscus or mesenteric injury. CT has better sensitivity but may still miss significant hollow viscus injuries because free fluid in the abdomen or air in the peritoneum may not be visualized immediately. Even with a high index of suspicion and admission of the patient for serial examination and observation, these injuries will sometimes be missed. Patients with hollow viscus injuries are treated in the operating room, as are unstable patients with mesenteric injuries. A stable patient with a mesenteric injury may be admitted to the hospital and observed rather than undergo exploratory laparotomy.

Injuries to the bladder and urethra are uncommon in children. A child with gross hematuria and no CT evidence of kidney injury should undergo retrograde urethrography to evaluate for rupture of the bladder or a torn urethra. Injuries to the urinary collecting system require emergency evaluation by a pediatric urologist.

**DISPOSITION**

Children with abdominal trauma who are suspected of having intraabdominal injury and in whom the results of ED evaluation are otherwise negative for injury are generally admitted to the hospital for observation. Children without other indications for admission and in whom abdominal CT findings are normal may be considered for discharge from the ED if they are free of pain, tolerate a regular diet, and have a responsible adult parent or guardian.

**REFERENCES**

REFERENCES

An estimated 615,000 traumatic brain injuries (TBIs) occur each year in patients younger than 19 years; this figure accounts for 26% of pediatric hospitalizations and 15% of all pediatric deaths. Children 0 to 4 years of age and older adolescents 15 to 19 years of age are most likely to sustain a TBI. Mild traumatic brain injury (mTBI), or concussion, represents the predominant form of acquired brain injury and accounts for 75% to 90% of all instances.

The mechanisms of pediatric TBI are similar to those in adults, with falls being the most common cause. However, child abuse must be considered as an occult mechanism of head injury in preverbal children because abusive head trauma remains the most common cause of traumatic death in infancy. Findings in such patients may be subtle, with nonspecific symptoms (vomiting, fussiness) and no history of trauma. Clinicians must maintain a high index of suspicion for inflicted injury in young children. In older adolescents, sports are a common cause of concussive injury, and return to sports should be addressed in the discharge instructions.

As in adults, the pathophysiology of pediatric head trauma is related to the degree of force. With moderate force, injury can occur to the brain parenchyma, which primarily results in nonoperative lesions, or can involve vascular structures, which typically results in operative lesions.

Patients younger than 2 years are at higher risk for skull fractures, with the most common type being linear fractures. In infants, fractures may occur even after short falls (≤3 to 4 feet). The majority of fractures have an overlying hematoma or swelling; only 15% to 30% are associated with an intracranial injury. In general, linear skull fractures heal without incident. Rarely, in children with open fontanelles (<2 years old) and fractures with greater than 3-mm separation, a tear in the dura allows pulsation of cerebrospinal fluid (CSF) or herniated meninges, which impedes fracture healing and extends the fracture over time. This may become apparent months to years after the initial injury and usually requires surgical correction. Depressed skull fractures with greater than 5 mm of depression generally require surgical correction. Basilar skull fractures have classic findings on physical examination (raccoon eyes, Battle sign, hemotympanum) and may be associated with cranial nerve palsies (facial palsy, nystagmus, diplopia, and facial numbness), CSF rhinorrhea or otorrhea, and hearing loss.
After a minor head injury in children, it is necessary to rule out significant intracranial injury. Studies have shown that approximately 6% of children with minor head injury have abnormal findings on CT and, more important, that less than 1% require neurosurgical intervention. When compared with the adult population, pediatric patients are more likely to be seen in the ED following very mild injury, thus further lowering the pretest probability of significant intracranial injury.

Given this tendency, many studies have sought to identify criteria that would guide the use of neuroimaging in pediatric populations. A recent study by the Pediatric Emergency Care Applied Research Network (PECARN) assessed 42,000 pediatric patients to develop a decision rule. For children 2 years or younger, they found that patients with abnormal mental status, non–frontal scalp hematoma, loss of consciousness, a severe mechanism of injury, and a palpable skull fracture and those who were not “acting normally” per parent could be accurately predicted to have significant intracranial injury. For patients older than 2 years, they found abnormal mental status, loss of consciousness, significant vomiting, severe mechanism of injury, clinical signs of basilar skull fracture, and severe headache predicted significant intracranial injury (Fig. 24.1). Use of these clinical guidelines would significantly reduce unnecessary intracranial imaging.

Observation is an alternative to neuroimaging in patients with mild injury. A retrospective Canadian study of approximately 17,000 pediatric patients older than 8 years found that delayed deterioration (>6 hours) occurred in no patients with a normal GCS score. Pediatric patients are often evaluated several hours after their injury; continued observation within the department or at home would be an acceptable alternative to emergency imaging in low-risk patients.

For patients with mTBI or concussion, emergency department (ED) clinicians in general have not focused on the morbidity associated with this injury and may not recognize their ability to improve patient outcomes. It has been shown that accurate assessment of the severity of the injury and consequent outpatient guidance and management may decrease recovery time, reduce the risk for secondary complications, and improve outcomes. mTBI or concussion can also be challenging to diagnose. Patients with polytrauma or other significant injury may not be screened for the subtle findings associated with concussion, which can result from any blow to the head or an indirect force through the neck or to the body. The immediate symptoms of concussion are the result of trauma-induced alterations in neurologic function and include amnesia (retrograde or anterograde), altered consciousness (loss of consciousness, dazed, stunned, confused), migrainelike symptoms (headache, nausea, photophobia or phonophobia, visual changes, dizziness or balance problems), cognitive symptoms (difficulty concentrating or remembering), and changes in personality. These immediate symptoms are typically short-lived and are associated with a normal findings on physical examination and neuroimaging. Clinicians in the ED are in a unique position to diagnose mTBI and initiate proper management to minimize the adverse outcomes of concussion.

### Treatment

With severe or moderate injury, initial pediatric management is similar to adult management. The primary focus is to protect the airway, maintain hemodynamic stability, and identify patients with more significant intracranial injury. Patients with severe TBI require early consultation with a pediatric neurosurgeon or transport to a pediatric trauma center (or both). Early surgical intervention and initiation of intracranial pressure monitoring have been shown to improve long-term outcomes.

### Admission and Discharge

The majority of patients with mTBI or concussion are reassured and discharged home. For these patients, appropriate diagnosis, patient education, and outpatient management may decrease recovery time, reduce the risk for secondary complications, and improve outcomes. Pediatric patients with normal neuroimaging findings but persistently abnormal GCS scores, severe vomiting, or unremitting headache should be admitted to the hospital for observation and hydration.

Determining concussion severity and recovery is critical because returning patients to physical activities too soon following concussion can lead to disabling and even life-threatening outcomes such as second impact syndrome, which is the sudden onset of cerebral edema after a second (even minor) concussion. Historically, however, evaluation and management of victims of concussion have been inconsistent. To add to the confusion, more than 25 concussion grading systems exist, each with their own ranking of concussion severity and management recommendations. Unfortunately, these clinical grading systems are not validated and have not allowed clinicians, patients, or families to recognize the spectrum of postconcussive symptoms.

The Centers for Disease Control and Prevention has recently changed its recommendations for acute concussion management from the use of grading scales to use of the Acute Concussion Evaluation (ACE) (see ACE and ACE-Care Plan, available at [www.cdc.gov](http://www.cdc.gov)). The ACE is a paper evaluation form that was designed to provide a diagnostic framework for...
Suggested computed tomography (CT) algorithm for children younger than 2 years (A) and for those aged 2 years and older (B) with Glasgow Coma Scale (GCS) scores of 14 to 15 after head trauma. (From Kuppermann N, Holmes JF, Dayan PS, et al. Lancet 2009;374:1160-70.) ciTBI, clinically important traumatic brain injury; LOC, loss of consciousness.

Fig. 24.1

Clinicians in the outpatient setting to define concussion and characterize the patient’s symptoms. Rather than focus on grading assessments of concussion severity, the ACE provides a standardized tool to aid in identifying mTBI in primary care settings. Unlike grading systems that provide set return-to-play decisions (e.g., those with grade 1 concussion may return to play in 15 minutes), the ACE offers an ACE-Care Plan, a set of best-practice discharge instructions that strongly recommend rest and endorse the “Stepwise Return to Play” (Box 24.1). The ACE-Care Plan also offers extensive information regarding return to school and work to minimize overexertion and improve recovery. The ACE and ACE-Care Plan represent a transition from passive management to active evaluation of concussion and intervention to decrease secondary injury.

Most patients with mTBI will recover within the first 7 to 10 days. In others, postconcussive syndrome will develop, a constellation of neurocognitive symptoms (including headaches, fatigue, sleep problems, changes in personality, photophobia, hyperacusis, dizziness, and deficits in short-term memory and problem solving) that may persist for days to weeks. Athletes who suffer multiple concussions are more likely to be plagued with postconcussive symptoms. School performance may be affected in these children, and some may need specific accommodation plans. Patients at high risk for complications related to mTBI (e.g., athletes, those with previous concussions or personal history of migraines) should be evaluated by a concussion specialist.

Occasionally, patients with postconcussive syndrome return to the ED for subsequent problems. In patients with waxing and waning postconcussive symptoms or migraine headache, emergency imaging is not necessary except to exclude alternative diagnoses. Postconcussive symptoms respond well to...
standard migraine treatment (nonsteroidal antiinflammatory drugs, intravenous fluids, antiemetics). These patients should be referred to a concussion specialist for follow-up.

**KEY POINTS**

- Ligaments are stronger than bones in young children.
- The history should be consistent with the injury and the developmental stage of the child.
- Children are poor at localizing pain and often refer symptoms to neighboring joints. The pathologic site in knee pain may be the hip.
- Growth plate injuries are subtle but have the potential to lead to growth arrest.
- Radiographs of the contralateral side are useful as comparison views for the investigation of subtle fractures.

Pediatric musculoskeletal trauma and infections are a major cause of morbidity, including growth arrest, limb deformity, chronic pain, and arthritis. Investigation of pediatric orthopedic injuries and conditions requires knowledge and understanding of the unique childhood bony anatomy. To maximize normal growth and development, the emergency physician should be mindful of physeal injuries, bone-remodeling potential, and unique pediatric orthopedic conditions.

**FRACTURES**

Trauma to immature and incompletely ossified bones results in unique pediatric orthopedic injuries, including torus, greenstick, bowing, and physeal fractures. These patterns do not occur in dense adult bone. Because the radiographic findings of some of these abnormalities are incredibly subtle, comparison views are particularly helpful. Trauma that would result in sprains and strains in structurally mature individuals causes the thick periosteum to be torn from the bony cortex and resultant avulsion fractures. Ligamentous tears are uncommon in children because their ligaments are stronger than the neighboring bones.

Children’s bones are apt to bend with a fracture on only one side of the periosteum. Callus formation and remodeling are extensive in pediatric injuries and contribute to the faster healing found in children. The goal of reduction should always be nearly perfect alignment, and growing bones have a dramatic potential for spontaneous correction.

Pediatric bones are less dense and therefore more prone to compression or bending when an axial load is applied. Falls onto an outstretched arm may result in torus or buckle fractures (Fig. 25.1). Greenstick fractures are incomplete, with the cortex remaining intact on one surface. To obtain complete

**RADIAL HEAD SUBLUXATION**

Radial head subluxation, or nursemaid’s elbow, is a common injury that affects children between the ages of 6 months and 5 years. It results from hyperextension with subluxation of the radial head and acute interposition of the annular ligament into the radiocapitellar joint. A history of longitudinal traction may not be obtained because the caretaker may not be aware of a particular event or may feel guilty about causing the child’s injury. A concern about wrist or shoulder injury may be reported because inadvertent manipulation of the injured elbow caused pain.

**PRESENTING SIGNS AND SYMPTOMS**

Children refuse to use the affected arm and hold it close to the body and in slight flexion. They do not appear to be in particular distress but may be fearful that examination will elicit pain. There is no tenderness with palpation or bony or soft tissue abnormality. Radiographs are unnecessary unless another particular injury is suspected. Edema and tenderness are present with supracondylar fractures.

A number of reduction techniques are used, including the hyperpronation method and the supination-flexion method. The hyperpronation method has proved more effective and appears to be less traumatic.1 With the arm held in extension, the wrist is hyperpronated and a click is sometimes heard. In the supination-flexion approach the examiner places the thumb of one hand over the radial head and provides countertraction. Next, while holding the wrist, the elbow is pulled into extension. The final phase is supination and flexion at the elbow. Most children return to full functioning within 15 minutes, and the child should be observed until full range of motion is regained.

When multiple reductions fail, radiography should be considered. In a child with failed reduction and negative radiographic findings, a sling or posterior splint is necessary with close orthopedic follow-up.
Pediatric Orthopedic Emergencies

CHAPTER 25  PEDIATRIC ORTHOPEDIC EMERGENCIES

They require splinting and generally carry a good prognosis. Types III and IV are intraarticular fractures that also involve the growth plate. In a type III injury, the fracture line extends through the epiphysis into the physis. In type IV, the fracture passes through the epiphysis, physis, and metaphysis. Types III and IV carry a risk for growth retardation, altered joint mechanics, and functional impairment and thus require urgent orthopedic evaluation. Type V fractures are compression injuries and are difficult to visualize on radiographs. The diagnosis is often made retrospectively following a case of growth arrest.

TODDLER’S FRACTURES

Toddler’s fractures are nondisplaced oblique or spiral fractures through the distal end of the tibia. Questioning may not reveal any significant injury, just that the child might refuse to bear weight after a day playing at the park. Findings on physical examination can range from entirely benign to diffuse tenderness along the tibial shaft. The absence of edema and ecchymosis is commonplace and not surprising. Gentle twisting of the lower part of the leg may elicit pain as the fracture plane is opened. Radiographic findings are subtle, and multiple views, including anteroposterior (AP), lateral, and oblique images, may be necessary. In the event of negative findings, a bone scan may be considered.

If the symptoms persist, one may choose to repeat the films in 7 to 10 days to look for new subperiosteal bone formation. Immobilization is sufficient to promote healing. When the child limps and radiographic findings are negative, a fracture or injury in another location should be considered. Varied pathology, including appendicitis, toxic synovitis, septic arthritis, foot and ankle fractures, soft tissue injuries, and abuse (Box 25.1), may all be manifested as a limp in a toddler.

SUPRACONDYLAR FRACTURES

Supracondylar fractures are the most frequent elbow fractures in children and often occur in children 3 to 10 years of age. The most common mechanism is a fall onto an outstretched hand with the elbow hyperextended.

Classification of the types of supracondylar fractures is based on the extent of the injury: type I is nondisplaced (Fig. 25.4), type II is displaced posteriorly with an intact cortex...
Fig. 25.4 Type I supracondylar fracture. The anterior humeral line does not intersect with the capitellum. A subtle fracture is visible along the anterior surface of the humerus.

Fig. 25.5 Type II supracondylar fracture.

Fig. 25.6 Type III supracondylar fracture.

(Fig. 25.5), and type III is completely displaced with no cortical contact (Fig. 25.6). Type I injuries are managed by immobilization for 4 to 6 weeks. Treatment of type II injuries is based on the extent of the damage, and an orthopedist should be consulted. More severe cases require admission, reduction, and internal fixation, but milder cases may be treated as type I injuries. All type III fractures require closed reduction with pinning in the operating room.

Radiographic findings may be subtle, particularly in type I injuries (Box 25.2). When a fracture line cannot be visualized easily, other findings may assist in making the diagnosis. A posterior fat pad or joint effusion located dorsal to the distal end of the humerus at the level of the olecranon fossa is always pathologic and evidence of a fracture. An anterior fat pad is normal unless it is lifted up and squared off inferiorly into a “sail sign.” A line drawn along the anterior surface of the humerus should intersect the capitellum in its middle third. Posterior displacement of the distal end of the humerus will cause the line to fall further anteriorly or miss the capitellum entirely.

BOX 25.1 Fractures Suggesting Abuse*

Multiple fractures, especially in various stages of healing
Fracture patterns inconsistent with the history
Fractures coexistent with soft tissue injuries consistent with abuse
Metaphyseal chip fractures
Lower-extremity fractures in nonambulatory children
Spiral fractures of the humerus
Multiple depressed skull fractures
Rib fractures, especially multiple posterior fractures

*A skeletal survey should be done in all cases of suspected abuse.
LEGG-CALVÉ-PERTHES DISEASE

Legg-Calvé-Perthes disease is characterized by avascular necrosis and resorption of the femoral head. Its onset occurs in children between 4 and 9 years of age, and it is more common in overweight boys. Although the definitive etiology is unknown, research has focused on clotting abnormalities and increased blood viscosity.

PRESENTING SIGNS AND SYMPTOMS

The disease is initially clinically silent and may come to medical attention incidentally as a result of trauma. The onset of symptoms is usually insidious. Pain may be present in the hip or be referred to the hip, knee, anterior aspect of the thigh, or groin. Tenderness is rarely present, and symptoms include an antalgic gait with decreased hip abduction and medial rotation.

DIAGNOSTIC TESTING

AP and frog-leg views of the pelvis allow optimal visualization of the femoral head. Disease findings include widening of the articular cartilage, subchondral fractures, irregularity, and flattening of the epiphysis.

TREATMENT AND DISPOSITION

Treatment includes pain management with nonsteroidal anti-inflammatory drugs (NSAIDs) and referral to a pediatric orthopedic surgeon. The majority of children with this disease do well with observation and nonsurgical intervention.4

SEPTIC ARTHRITIS

Septic arthritis is a true medical emergency that requires early intervention to prevent permanent joint destruction. The joint space is invaded by microbes as a result of hematogenous seeding, local spread from neighboring infection, or direct inoculation from trauma or surgical infection. Bacterial enzymes cause direct tissue destruction. Synovial edema, increased synovial fluid production, and pus increase intraarticular pressure, which causes damage to vessels and articular cartilage. Commonly involved organisms are Staphylococcus aureus and assorted Streptococcus species. Group B streptococci and Escherichia coli are important causes in neonates, and gonococcal arthritis should be a serious consideration in sexually active adolescents.

PRESENTING SIGNS AND SYMPTOMS

Children suffering from septic arthritis are frequently ill appearing with a fever of 104° F (40° C) or higher, limited range of motion in the affected joint, and pain and swelling.5 The pain is constant and increases with movement. In the case of septic arthritis of the hip, the child lies in a position of comfort with the hip slightly flexed, abducted, and externally rotated. An infected knee will be erythematous, edematous, warm, and tender to palpation.

DIAGNOSTIC TESTING

Plain radiographs, a complete blood count, erythrocyte sedimentation rate, C-reactive protein, and blood culture are necessary in the evaluation of children with suspected septic

With more severe injuries, the difficulty is not in making the diagnosis but rather recognition and reduction of complications. Morbidity includes range-of-motion abnormalities, neurovascular compromise, and long-term deformities. A thorough examination and documentation of neurovascular status, pain control, and stabilization are mandatory. The limb should be splinted in the deformed position. Motor and sensory function of the median, ulnar, and radial nerves is at risk. Direct vascular injury is uncommon, but because a potential for compartment syndrome does exist, examinations should be repeated frequently and recorded.3

SLIPPED CAPITAL FEMORAL EPIPHYSIS

A slipped capital femoral epiphysis affects boys twice as commonly as girls. In most children the condition is diagnosed early in their growth spurt, with boys being affected at 13 to 15 years and girls at 11 to 13 years of age (because of girls’ earlier onset of pubertal development). Obesity is a risk factor, but slipped capital femoral epiphysis develops in many average-sized children.

PRESENTING SIGNS AND SYMPTOMS

Pain and limp are the most common reasons for seeking care in the emergency department, and symptoms may have been present for weeks to months. Pain, which can range from dull and intermittent to severe and persistent, can be present in the hip or referred to the knee, groin, or anterior aspect of the thigh. Sometimes a history of trivial trauma prompts medical evaluation. Physical examination reveals a hip in flexion with mild external rotation. Range of motion is limited, especially full flexion, medial rotation, and internal rotation.

DIAGNOSTIC TESTING

Radiographic studies should include both AP and frog-leg views because an AP view alone may miss the diagnosis. On the AP view of a normal hip, a line drawn along the superior margin of the femoral neck cortex should transect the epiphysis by a small margin. With a slipped capital femoral epiphysis, the line passes outside the epiphysis or just at the superior edge. Contralateral images or full pelvic views are helpful; however, up to 25% of cases of slipped capital femoral epiphysis are bilateral.

TREATMENT

Diagnosis of slipped capital femoral epiphysis necessitates urgent orthopedic evaluation. Management is surgical and consists of placing screws through the femoral neck into the epiphysis. Delay in diagnosis or management may lead to avascular necrosis and long-term disability.

BOX 25.2 Radiographic Evidence of Supracondylar Fractures

Direct fracture visualization
Posterior fat pad
Sail sign
Joint effusion
Malalignment of the anterior humeral line
arthritis. Radiologic findings include joint space widening, soft tissue swelling, and displacement of adjacent fat pads. Comparison views may be helpful if the difference of only a few millimeters from the teardrop of the acetabulum to the medial metaphysis of the femoral neck may be significant. In young children, lack of ossification limits the usefulness of radiographs, and ultrasonography provides more detail.

A convincing clinical or laboratory picture justifies joint aspiration for fluid analysis, including protein, glucose, Gram stain, and culture. Joint fluid yields a positive culture in approximately 50% to 75% of cases. Blood culture is much less effective and is positive in approximately one third of cases.

**TREATMENT**

Definitive therapy is intravenous administration of antibiotics and surgical drainage of purulent material from the joint. Because the potential for joint destruction is great and the yield of Gram stain is low, empiric antibiotic therapy in the emergency department is indicated. Coverage should include an antistaphylococcal agent, either a β-lactamase–resistant penicillin, clindamycin, or a first-generation cephalosporin. Gram-negative coverage should also be considered for neonates.

**TOXIC SYNOVITIS**

Toxic, or transient, synovitis is a benign, self-limited inflammatory condition. A postinfectious inflammatory response has been suggested as the possible cause, but no definitive etiology has been determined. It affects children 3 to 10 years of age, and its findings mimic those of septic arthritis. The joints most often involved include the hip and knee. Fever is rarely present, but when it does occur, it is usually low grade.

**PRESENTING SIGNS AND SYMPTOMS**

Although patients will sit in a position of comfort and complain with movement of the limb, the affected joint has full range of motion. This is in stark contrast to septic arthritis, in which the child appears systemically ill, is in significant pain, and cannot move the affected joint through full range of motion.

**DIAGNOSTIC TESTING**

The white blood cell count, erythrocyte sedimentation rate, and C-reactive protein findings are usually normal or slightly elevated, consistent with an inflammatory process. Radiographs are often normal or may reveal a mild effusion with joint space widening. Because sufficient overlap exists in some manifestations of septic joint and toxic synovitis, synovial fluid is necessary to make the diagnosis (Table 25.1). When obtained, synovial fluid is sterile.

**TREATMENT**

Treatment is directed at relief of symptoms with NSAIDs on an outpatient basis. Pain usually lasts 3 to 4 days but may persist for a few weeks. Children return to full activity with no associated morbidity.

concentration of cones. The optic nerve is located behind the retina and is responsible for transmitting signals from the photoreceptor cells to the brain (Fig. 26.1).

The extraocular muscles (Fig. 26.2) help in stabilization of the eye. Six extraocular muscles assist in horizontal, vertical, and rotational movement. These muscles are controlled by impulses from cranial nerves III, IV, and VI, which tell the muscles to relax or contract.

GLAUCOMA

EPIDEMIOLOGY

More than 3 million Americans suffer from glaucoma, the leading cause of preventable blindness in the United States. The term glaucoma refers to a group of disorders that damage the optic nerve and thereby lead to loss of vision. The two main classifications of glaucoma are open angle and angle closure. Acute angle-closure glaucoma is more common in white persons and women. Its peak incidence occurs between the ages of 55 and 70. African Americans, patients older than 65 years, and people with diabetes and ocular trauma are at increased risk for open-angle glaucoma. Differentiation between the two types of glaucoma lies in the mechanism of obstruction of outflow, as described later. Intraocular pressure (IOP) is determined by the rate of aqueous humor production relative to its outflow and removal. Normal IOP is between 10 and 20 mm Hg. This discussion focuses mainly on acute angle-closure glaucoma.

When the angle of the anterior chamber is reduced, outflow of aqueous humor is blocked, which results in elevated IOP and ultimately visual compromise. Patients with a shallow anterior chamber, hyperopic (farsighted) eyes, and eyes with lens abnormalities such as cataracts are more prone to acute angle-closure glaucoma. Pupillary dilation, caused by events such as presence in a dark room, is the most significant event that can cause an acute attack of glaucoma because the flaccid iris can be pushed against the trabecular meshwork and result in obstruction.

PRESENTING SIGNS AND SYMPTOMS

Patients with acute angle-closure glaucoma may have a sudden onset of headache or eye pain. Occasionally, nausea and vomiting from vagal stimulation can be the dominant symptoms. Shortly after the onset of pain, blurry vision or halos in the visual field may occur.
The classic physical findings are unilateral eye injection, especially at the limbus; a nonreactive, midsize pupil; shallow anterior chamber; corneal edema or haziness; and high IOP (often 60 to 90 mm Hg). If the attack has been prolonged, ischemia of the ciliary body reduces aqueous humor production with a resultant decrease in IOP. This process is especially important because the ultimate damage depends on the duration of the attack rather than the severity of the elevation in pressure.

With open-angle glaucoma, development of the disease is usually insidious, bilateral, slowly progressive, and painless.

**MEDICAL DECISION MAKING**

Visual acuity should be recorded in both eyes. Examination of the eye should include a search for the classic signs of glaucoma already described, including a middilated pupil in the
from the carotid artery that lodges in a distal branch of the ophthalmic artery. Central retinal artery occlusion most commonly affects elderly patients and men. Although most emboli are formed from cholesterol, they may also be calcific, fat, or bacterial from cardiac valve vegetations.

**PATHOPHYSIOLOGY**

The visual complaints and deficits resulting from retinal artery disease are caused by ischemia. In addition to the embolic causes already described, low-flow states and vasospasm may have the same visual consequences.

**PRESENTING SIGNS AND SYMPTOMS**

Sudden, painless visual loss is the classic manifestation of central retinal artery occlusion. Sometimes patients report transient visual loss before complete compromise. The visual loss is usually profound. Examination can often elicit an afferent pupillary defect (when light is shined into the abnormal eye, the pupil of the affected eye paradoxically dilates instead of constricting). Funduscopic examination typically demonstrates a pale retina with a cherry-red spot at the fovea (Fig. 26.3). Complete evaluation involves auscultation of the carotid arteries for bruits, palpation of the temporal artery for tenderness, and cardiac auscultation and palpation of the pulse to detect atrial fibrillation.

**DIFFERENTIAL DIAGNOSIS**

Sudden, painless visual loss can also result from central retinal vein occlusion, temporal arteritis, ischemic optic neuropathy, amaurosis fugax, retinal detachment, or vitreous hemorrhage. If the loss of vision is accompanied by pain, arterial dissection should be part of the differential diagnosis. The presence of a headache, temporal artery tenderness, and an elevated erythrocyte sedimentation rate (ESR) suggests temporal arteritis. Amaurosis fugax, or unilateral transient obstruction of a retinal artery, does not cause visual loss lasting longer than 15 minutes. Ischemic optic neuropathy causes optic disk pallor and elevation. Retinal detachment and vitreous hemorrhage

**TREATMENT**

Acute angle-closure glaucoma is an ophthalmologic emergency. Because outcome depends on the duration of elevated IOP, treatment should be initiated promptly. Therapy is geared toward decreasing aqueous production, increasing aqueous outflow, and reducing vitreous volume to lower IOP.

Initial treatment includes a topical, nonselective beta-blocker such as 0.5% timolol to reduce aqueous production. Topical beta-blockers are absorbed and can cause systemic effects. Intravenous administration of a carbonic anhydrase inhibitor such as acetazolamide, 500 mg, will also rapidly reduce aqueous humor production. Intravenous mannitol will create an osmotic gradient between the vitreous and blood and thereby cause a reduction in vitreous volume, so it may be useful for severe cases. Tonometry can be performed frequently, even every 15 minutes, to assess progress.

Topical 2% pilocarpine is used to help reopen the angle. Miotics such as the direct-acting parasympathomimetic agent pilocarpine might be less effective at very high IOP because the iris is relatively ischemic and therefore less responsive. Sometimes pilocarpine is used after IOP has been reduced to less than 40 mm Hg. Pilocarpine will therefore be more effective as the initially high pressures are reduced with the initial beta-blocker drops and acetazolamide. Topical 1% prednisolone acetate may sometimes be added to reduce inflammation. For ongoing treatment, topical 2% pilocarpine and prednisolone acetate may be administered every 6 hours and oral acetazolamide two times per day. Sedatives and antiemetics may be administered as needed. When the inflammation has been reduced sufficiently, the patient will be taken for iridotomy by the ophthalmologist.

**DISPOSITION**

Disposition of the patient is determined in conjunction with the consulting ophthalmologist. Indications for admission include intractable nausea and vomiting and need for careful monitoring to administer systemic agents.

**CENTRAL RETINAL ARTERY OCCLUSION**

**EPIDEMIOLOGY**

Retinal artery occlusion affects less than 1 per 100,000 persons annually. It is most commonly caused by an embolus
result in visual disturbances such as floaters in addition to the loss of vision—the occurrence of which is variable with a detached retina. Vitreous hemorrhage causes absence of the normal red reflex of the fundus. A neurologic etiology such as a cerebral infarct must also be considered.

**TREATMENT**

Treatment must be initiated immediately because the visual loss is generally irreversible after 2 hours of ischemia. Regardless, the outcome is generally poor. Several approaches may be used. Intermittent globe massage can be performed in an effort to dislodge the clot and propel it distally: moderate pressure is applied for 5 second and then released for 5 seconds, and the cycle is repeated. The use of anterior chamber paracentesis for visual loss is based on the principle that decreased IOP allows better perfusion of the retinal artery and may propell the clot distally. Acetazolamide can be administered intravenously for the same purpose. Inhaled carbogen (mixture of 95% oxygen and 5% carbon dioxide) can be used to dilate the vasculature and thereby increase retinal PO2.

Other treatment options are intraarterial thrombolysis and hyperbaric oxygen; however, studies have shown limited improvement in visual outcome with early administration of both these treatment modalities.8,9 One retrospective study found that even with thrombolysis, vision did not improve to better than 20/300 in the affected eye.1 Another study investigated the outcomes of 32 patients with central retinal artery occlusion, 17 of whom underwent fibrinolysis.6 This study found that all but six of the treated patients reported improvement in their visual compromise but that only five of the untreated patients had any improvement. In this study, patients with a duration of symptoms of up to 24 hours were treated. Patients with sudden visual loss are admitted to the hospital so that the underlying cause can be sought.

**CENTRAL RETINAL VEIN OCCLUSION**

**EPIDEMIOLOGY**

Patients older than 50 years who have cardiovascular disease, hypertension, glaucoma, venous stasis, hypercoagulable conditions, collagen vascular diseases, or diabetes are at risk for central retinal vein occlusion.1

**PATHOPHYSIOLOGY**

Two types of retinal vein occlusion are distinguished, ischemic and nonischemic. The ischemic type is also known as hemorrhagic retinopathy, and the nonischemic type is also called venous stasis retinopathy. The manifestations and physical findings differ according to the type of occlusion involved.

**PRESENTING SIGNS AND SYMPTOMS**

Typically, patients with ischemic retinal vein occlusion report an acute and relatively profound decrease in visual acuity.
have been conducted to determine the benefit of steroids in treating both forms of retinal vein occlusion. Jonas et al. conducted a prospective, comparative, nonrandomized clinical interventional study to evaluate the visual outcomes in 32 patients with central retinal vein occlusion after intravitreal administration of triamcinolone acetate. The study included patients with both the ischemic and nonischemic forms of retinal vein occlusion. These researchers found that the medication resulted in temporary (up to 3 months) improvement in visual outcome but also raised IOP. Anticoagulants are not recommended because they may propagate hemorrhage.

**OPTIC NEURITIS**

**EPIDEMIOLOGY**

Optic neuritis is inflammation of the optic nerve, and visual loss is due to focal demyelination of the optic nerve. Most affected patients are between 15 and 40 years of age. This disorder can be associated with numerous diseases, including sarcoidosis, systemic lupus erythematosus, measles, leukemia, syphilis, and alcoholism; however, it is most commonly associated with multiple sclerosis. In fact, in up to a third of patients with optic neuritis, multiple sclerosis is eventually diagnosed, and approximately two thirds of patients with multiple sclerosis have optic neuritis. Optic neuritis can also be idiopathic.

**PATHOPHYSIOLOGY**

Optic neuritis results from an autoimmune reaction that ultimately causes demyelinating inflammation. In idiopathic and multiple sclerosis–related optic neuritis, lesions are characterized by areas of loss of the myelin sheath with preservation of axons. In acute disease, remyelination may occur. In chronic disease, because of the accumulation of scar tissue, the process becomes irreversible. The lesions in multiple sclerosis–associated optic neuritis are pathologically the same as those in the brain.

**PRESENTING SIGNS AND SYMPTOMS**

Symptoms of optic neuritis are generally unilateral. Patients complain of pain, especially with eye movement. Visual loss, which can range from minimal loss to complete loss of light perception, usually occurs over a number of hours or days. Patients may also experience dulling of color vision, worse vision after exertion or exposure to steam, brief light flashes, and central scotoma. An afferent pupillary defect is always present. Funduscopic examination may show disk pallor, swelling, or elevation. However, because up to two thirds of cases are retrobulbar, the fundus can appear normal.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Any condition that causes visual disturbance along with eye pain must be considered in the differential diagnosis of optic neuritis. Orbital cellulitis can cause this clinical picture but does not include an afferent pupillary defect; furthermore, inspection alone should allow differentiation between the two diseases. Glaucoma can also cause the combination of ocular pain and visual impairment. Physical examination, including assessment of pupil size and reactivity, as well as corneal inspection, allows distinction between glaucoma and optic neuritis.

Unilateral ocular pain with visual compromise should always raise clinical suspicion for optic neuritis. If no afferent pupillary defect is found on physical examination, another diagnosis is almost ensured. Although imaging is usually not indicated, magnetic resonance imaging (MRI) provides adequate visualization of the optic nerve.

**TREATMENT AND DISPOSITION**

Ophthalmologic and neurologic consultation should be obtained if optic neuritis is suspected. Approximately 31% of patients with optic neuritis have a recurrence within 10 years of the initial episode. The goals of treatment are to restore visual acuity and prevent propagation of the underlying disease process. The Optic Neuritis Treatment Trial was a randomized, 15-center clinical trial involving 457 patients that was performed to evaluate both the benefit of corticosteroid treatment of optic neuritis and the relationship of this entity to multiple sclerosis. Use of intravenous steroids in conjunction with oral steroids reduced the short-term risk for the development of multiple sclerosis as determined by MRI evaluation. No long-term immunity from or benefit for multiple sclerosis was reported, however. The study concluded that although intravenous steroids have only minimal, if any effect on the patient’s ultimate visual acuity, they do expedite recovery from optic neuritis. Use of oral steroids alone is associated with a higher recurrence rate of optic neuritis. The dosage regimen recommended on the basis of the study results was methylprednisolone, 250 mg intravenously every 6 hours for 3 days, followed by prednisone, 1 mg/kg/day orally for 11 days.

**RETINAL DETACHMENT**

Retinal detachment is a true ophthalmologic emergency. Unfortunately, it is also relatively common and affects 1 in 300 people. Before the introduction of and improvement in a number of treatment modalities, this entity was uniformly blinding. Early diagnosis and treatment are imperative for preservation of vision. Retinal detachment may be associated with vascular disorders, congenital malformations, metabolic disarray, trauma, shrinking of the vitreous, myopia, degeneration, and less commonly, diabetic retinopathy and uveitis. It is generally more common in older patients. Three different types of retinal detachment are recognized, each associated with different conditions.

**PATHOPHYSIOLOGY AND ANATOMY**

The retina has two layers, the inner neuronal layer and the outer pigment epithelial layer (the choroid). Retinal detachment refers to separation of the two layers. Rhegmatogenous retinal detachment, the most common of the three types, is caused by a tear or hole in the neuronal layer, which leads to
extrusion of fluid from the vitreous cavity into the potential space between the two retinal layers. It is more common in patients older than 45 years and those with severe myopia. When caused by trauma, this type of detachment can affect any age group. Exudative retinal detachment is caused by leakage of fluid or blood from within the retina itself. Predisposing factors for this type include hypertension, vasculitis, and central retinal venous occlusion. Traction retinal detachment results from the formation and subsequent contraction of fibrous bands in the vitreous.

PRESENTING SIGNS AND SYMPTOMS

Retinal detachment can occasionally be asymptomatic. More commonly, patients complain of flashes of light, floaters, or fine dots or cobwebs in their visual fields. Generally, a new onset of floaters associated with flashing lights is indicative of retinal detachment unless proved otherwise. Visual acuity correlates with the extent of macular involvement and can be minimally changed to severely decreased. The loss of vision is usually sudden in onset and starts peripherally, with propagation to the central visual field. The visual loss is commonly described as a filmy, cloudy, or curtainlike appearance. Visual field cuts relate to the location of the retinal detachment, and an afferent pupillary defect occurs if the detachment is large enough. Retinal detachment is painless. On examination, the detached retina may appear gray or translucent or may seem out of focus (Fig. 26.5). Retinal folds may be seen. The visual field defects are variable, depending on the involvement of the retina and macula. Bedside ED ultrasonography has been shown to be helpful in confirming the presence of retinal detachment. Left untreated, all cases of retinal detachment progress to involve the macula and result in complete loss of vision in the affected eye.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Vitreous hemorrhage, which results from bleeding into either the preretinal space or the vitreous cavity itself, can be difficult to distinguish from retinal detachment. Complaints with this disorder range from floaters or cobwebs in the visual field to severe, painless loss of vision. Vitreous hemorrhage without concomitant retinal detachment should not, however, cause an afferent pupillary defect. Ophthalmoscopy usually demonstrates discoloration (ranging from reddish to black) with fundal structural details difficult to discern. Therapy for vitreous hemorrhage consists of bed rest with head elevation followed by possible interventional procedures such as laser photocoagulation and cryotherapy.

All macular disorders can cause painless visual loss. They are manifested as loss of central vision with preservation of peripheral vision, as well as findings of retinal abnormalities. A careful history and physical examination can exclude macular degeneration as a cause of central visual loss. Funduscopy examination in individuals with age-related macular degeneration shows the presence of drusen—small, yellow masses scattered on the retina. A gray-green subretinal neovascular membrane may also be seen. Inflammatory processes involving the retina often cause inflammatory proteins to fill the vitreous, thus making it appear cloudy.

TREATMENT

The sooner that treatment of retinal detachment is initiated, the greater the chance of visual preservation and recovery. After detachment, retinal ischemia ensues because of loss of the choroidal blood supply. Patients with suspected or confirmed retinal breaks or detachments require emergency ophthalmologic consultation. Contrary to traditional belief, not all detachments are managed surgically. Laser photocoagulation or cryotherapy is frequently used to create small burns around the area of detachment to prevent further leakage of fluid between the retinal layers. Intraocular gas is sometimes used to tamponade the tear. These procedures are approximately 95% effective in halting the disease process. Surgical intervention may be needed to repair the tear and simultaneously remove the traction forces on the retina. The modality of treatment is at the discretion of the consulting ophthalmologist.

TEMPORAL ARTERITIS

Temporal arteritis, an inflammatory condition that results from a generalized vasculitis of medium and large arteries, typically affects patients older than 50 years. This condition is also called giant cell arteritis. It has a female preponderance. Temporal arteritis occurs in as many as 1 in every 2000 people. Although mortality is not affected by the condition, it can cause blindness. Up to 75% of patients with visual compromise as a result of temporal arteritis would eventually experience contralateral visual impairment if not treated. Temporal arteritis is commonly, though not uniformly associated with polymyalgia rheumatica.

PATHOPHYSIOLOGY

Vessels affected by giant cell arteritis are infiltrated with lymphocytes, plasma cells, and multinucleated giant cells in patches or segmental patterns. A cell-mediated immune response is thought to account for the vascular changes seen with this disorder. Inflammation of branches of the
ophthalmic artery, especially the posterior ciliary artery, leads to ischemic optic neuritis, which compromises vision. The central retinal artery is also often affected. Inflammation of the temporal artery causes the classic headache associated with this diagnosis.

**PRESENTING SIGNS AND SYMPTOMS**

Unilateral headache, jaw or tongue claudication, constitutional symptoms, including anorexia and malaise, and visual impairment are common initial symptoms of temporal arteritis. Occasionally, the visual loss is preceded by amaurosis fugax. In one series of patients, visual loss was unilateral in 46%, sequential in 37%, and simultaneously bilateral in 17%. Patients with polymyalgia rheumatica may also complain of pain and stiffness in the shoulders or hips.

Examination may demonstrate tenderness and decreased pulsations over the involved temporal artery. Funduscopic findings may be normal or consist of optic disk edema or pulsations over the involved temporal artery. Funduscopic examination may demonstrate tenderness and decreased pulsations over the involved temporal artery. Funduscopic findings may be normal or consist of optic disk edema or pulsations over the involved temporal artery.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

In patients who do not have visual complaints, a differential diagnosis for headache must be investigated. Migraines, tension headaches, and subarachnoid hemorrhage may mimic temporal arteritis. Palpation of the temporal artery along with a careful history, including questions about jaw symptoms, may allow distinction. Because temporal arteritis is a medical emergency associated with high morbidity if not recognized and treated promptly, it must be definitely excluded on the basis of the history and physical or laboratory findings before the patient’s symptoms are attributed to another entity. Acute angle-closure glaucoma is also high on the differential diagnosis list, regardless of whether visual symptoms are present. Occasionally, headache can be the dominant symptom of glaucoma. In glaucoma, however, physical examination should find a mi.dilated, nonreactive pupil with corneal haziness and a shallow anterior chamber.

Although temporal arteritis can rarely be accompanied by a normal ESR, this parameter is almost always elevated. The upper limit of normal ESR increases with age. A rough approximation of the upper limit of normal for men is age in years divided by 2. For women it is age in years plus 10, with the sum divided by 2, or half the age in years plus 5. Elderly patients with new-onset headaches, visual loss, and an elevated ESR should always be treated for temporal arteritis. Generally, the ESR is higher than 80 mm/hr in individuals with temporal arteritis. Temporal biopsy confirms the presence of the disease. Early in the course of the disease, however, biopsy findings may be normal. Ultrasound has been proposed as a possible diagnostic modality for temporal arteritis, but studies have yielded conflicting results. Further investigation is necessary before a definitive conclusion can be drawn about its standard use.

**TREATMENT**

Treatment of temporal arteritis should never be delayed to await the results of biopsy because outcome is contingent on early medical treatment. Initial treatment should consist of prednisone, 60 to 80 mg, or high-dose intravenous methylprednisolone. The exact duration and regimen of steroid therapy are determined on a case-by-case basis. Generally, treatment is continued until the symptoms improve and the ESR begins to normalize. It has also been suggested that methotrexate, infliximab, and aspirin may also halt progression of the visual symptoms, but further studies are necessary to establish practice patterns.

**ORBITAL CELLULITIS AND PERIORBITAL CELLULITIS**

Without proper treatment, orbital cellulitis causes blindness and death in approximately 20% of patients. Because venous drainage of the orbital regions occurs through communicating vessels into the brain via the cavernous sinus, infection can progress rapidly with devastating consequences. Differentiation of orbital from periorbital (preseptal) cellulitis can be difficult but is important because the outcomes of the two entities—and therefore their treatments—are different.

**ANATOMY AND PATHOPHYSIOLOGY**

Orbital cellulitis is inflammation of any of the tissues within the orbit posterior to the orbital septum, whereas preorbital cellulitis is confined to the tissues anterior to the septum. Making this distinction is extremely important for management. Because of the gravity of the potential consequences of orbital cellulitis and the fact that most cases of orbital cellulitis have a concomitant periorbital component, the EP evaluating an infected, erythematous orbit should always assume that the patient has orbital cellulitis until it can be definitively excluded.

Approximately 75% of cases of orbital and periorbital cellulitis have identifiable antecedent causes. Sinusitis is the most common predisposing condition. Because the inferior, medial, and superior walls of the orbit lie adjacent to the sinuses, it is easy to understand how extension of infection may occur. The ethmoid sinus is most commonly involved. Infection after trauma or surgery with direct inoculation of pathogens and hematogenous spread from other sources of bacteremia are other methods of acquiring the infection. The pathogen involved is contingent on the mode of infection. Aerobic, non–spore-forming organisms are most frequently the culprits. Anaerobic organisms tend to be causative when infection results from chronic sinusitis.

**PRESENTING SIGNS AND SYMPTOMS**

Patients with infection limited to the periorbital tissues typically have erythema, edema, and warmth of the external eye tissues. Though generally unilateral, the infection can be
bilateral. Constitutional symptoms, including fever and malaise, may be present. The presence of ocular pain, ophthalmoplegia, and pain with extraocular movement suggests orbital involvement. Patients with orbital infection may also have decreased visual acuity and pupillary paralysis. Elevated IOP, preseptal (peri-orbital) cellulitis, conjunctival injection, and proptosis may additionally be present (Fig. 26.6).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The signs of periorbital infection can be similar to those of allergic periorbital swelling, especially when the involvement is bilateral. With an allergic reaction, cobblestoning may be noted on the interior aspect of the upper lid, and the condition should improve with the administration of diphenhydramine or another antihistamine. It can be difficult to distinguish orbital cellulitis from subperiosteal and orbital abscesses and even from cavernous sinus thrombosis, which carries a dismal prognosis. With subperiosteal abscesses, the globe is often displaced by the abscess; the displacement should be obvious on inspection. Orbital abscesses are located in postseptal tissues. They may cause obvious pus, significant ophthalmoplegia, and exophthalmos, as well as globe displacement. Cavernous sinus thrombosis typically starts unilaterally and progresses to contralateral involvement. Examination should detect dilation of the episcleral vessels and venous engorgement of the fundus; the pupil may be fixed and dilated. Depending on the time course, orbital neoplasm with associated inflammation may cause similar symptoms.

In many cases it may be possible to exclude orbital involvement on the basis of the history and physical examination alone. If there is any doubt or another entity or complication such as abscess is suspected, computed tomography (CT) is the diagnostic modality of choice. It is not necessary to use intravenous contrast material. MRI is another acceptable mode of diagnosis.

**TREATMENT AND DISPOSITION**

In adults, preorbital infection should be treated with oral antibiotics, and close outpatient follow-up should be arranged. An antibiotic that provides coverage for staphylococci, streptococci, and Enterobacteriaceae is appropriate. Orbital cellulitis should be treated with broad-spectrum intravenous antibiotics, the patient should be admitted to the hospital, and consideration should be given to incision and drainage if imaging reveals a collection. Because of the increased incidence of community-acquired methicillin-resistant *Staphylococcus aureus*, empiric coverage for this pathogen may also be considered. For periorbital infection in children, the threshold for admission to the hospital should be lower. Patients with mild periorbital cellulitis can be discharged with arrangements for extremely close outpatient follow-up. For patients with more involved cases, including any underlying comorbid conditions, admission for observation should be considered.

**THE RED EYE**

An injected, red eye signals an inflammatory reaction. Fortunately, most inflammation is self-limited and can be treated on an outpatient basis. The specific cause, treatment, course, and prognosis, as well as the impact on vision, depend on the underlying cause (Table 26.2).

This discussion focuses on conjunctivitis, the diagnosis in 30% of patients seen in the ED with ocular complaints and the most common cause of red eye. When the cornea is involved as well, the process is called keratoconjunctivitis.

**PATHOPHYSIOLOGY AND ANATOMY**

An eye appears red because of dilation of blood vessels. Ciliary injection, caused by dilation of branches of the anterior ciliary arteries, indicates inflammation of the cornea, iris, or ciliary body. Conjunctival injection results from dilation of the more posterior, superficial conjunctival vessels. Because of the conjunctiva’s more superficial location, vascular dilation causes more dramatic injection there than in the ciliary body.

Conjunctivitis refers to inflammation of the mucous membrane that lines the anterior sclera and inner eyelids. The conjunctiva is a key player in maintaining lubrication of the eye. Infection can result in scarring and abnormal tear formation in the affected eye.

Conjunctivitis can have a viral, bacterial, fungal, toxic, chemical, or allergic cause. The clinical findings and treatment differ with the underlying etiology. Sometimes it may be difficult to determine the underlying cause.

PRESENTING SIGNS AND SYMPTOMS

Generally, bilateral conjunctivitis signifies an infectious or allergic cause. However, such is not always the case. Viral infection is the most common cause of conjunctivitis. Adenovirus infection, which is highly contagious, is extremely common. Other viral causes include coxsackievirus and enteroviruses. Patients have significant injection, itching, irritation, and watery discharge. They may have accompanying preauricular adenopathy. Patients often have associated mild systemic symptoms because the conjunctivitis occurs in concert with a viral syndrome. Epidemic keratoconjunctivitis, which may result in the development of pseudomembranes, is caused by adenovirus types 8 and 19; this is the classic pink eye. Patients are contagious for up to 2 weeks.

Herpes simplex conjunctivitis is manifested as unilateral conjunctival injection with a clear discharge. Patients complain of a foreign body sensation and photophobia. With gross inspection alone it may be impossible to distinguish herpes simplex from other viral causes. Patients may have facial or lid vesicles. This infection can spread rapidly and cause corneal damage, which is seen as a dendritic pattern on fluorescein examination. Depending on the location, size, and depth of corneal involvement, patients may have decreased visual acuity.

Herpes zoster ophthalmicus is caused by activation of the virus along the ophthalmic branch of the trigeminal nerve. A vesicular rash is present along the involved dermomebrane and results in forehead and upper eyelid lesions. Lesions on the tip of the nose, called the Hutchinson sign, signify involvement of the nasociliary branch of the fifth cranial nerve. The presence of the Hutchinson sign indicates a much higher likelihood of ocular involvement (76% risk versus a 34% risk in the absence of such lesions). Fluorescein examination may show punctate, ulcerated, or dendritic corneal lesions (Fig. 26.7).

Patients with bacterial conjunctivitis have conjunctival erythema, a foreign body sensation, purulent drainage, and morning crusting of the eye. They do not usually experience photophobia or loss of visual acuity. The most common causative organisms are *Staphylococcus*, *Streptococcus*, and *Haemophilus* (although with immunization this last pathogen is being seen decreasingly).

Gonococcal infection generally results in unilateral conjunctival injection, copious purulent drainage, and edema and erythema of the lids. The infection is sudden in onset and progresses rapidly. Patient populations usually affected are infants, health care workers, and sexually active young adults. The amount of discharge helps distinguish gonococcal infection from other bacterial pathogens. Patients may have associated urethral discharge or arthritis.

*Pseudomonas aeruginosa* infection should be suspected in patients who are immunosuppressed or wear contact lenses. Usually, a sticky, mucopurulent, yellow-green discharge is present. The cornea should be inspected carefully for ulceration because corneal perforation with progression of the infection is a major concern with this organism.

Fungal pathogens that cause conjunctivitis include *Actinomyces*, *Aspergillus*, *Candida*, *Coccidioides*, and *Mucor* (in diabetic patients). These organisms should be considered in any immunosuppressed patient, as well as any individual who has sustained eye trauma involving vegetable matter. Examination may show a corneal infiltrate with underlying endothelial plaque and hypopyon, which is the presence of pus cells in the anterior chamber.

Chlamydial conjunctivitis is fairly common, especially in sexually active young adults. It is also a frequent cause of neonatal conjunctivitis. Patients may have associated gonococcal disease and should thus be asked about urethral discharge and arthritis. Patients with chlamydial conjunctivitis have a scant seropurulent eye discharge and fair to moderate conjunctival injection. Preauricular adenopathy is occasionally associated with this disorder.

Allergic conjunctivitis gives rise to significant pruritus and chemosis. Generally, an associated clear discharge is present in varying amounts. Cobblestoning may be seen on the inner eyelids.

DIAGNOSIS

The diagnosis of conjunctivitis is based on the history, physical examination, and appropriate exclusion of other causes of red eye. It is important, in the correct setting, to perform a thorough examination to rule out both other causes of red eye and potential complications of conjunctivitis such as corneal ulceration. When particularly virulent pathogens are a consideration, Gram stain and cultures may be necessary. Because the diagnosis of viral conjunctivitis can be made clinically, viral culture and laboratory investigation are not necessary.

TREATMENT AND DISPOSITION

Some basic tenets should be followed in the treatment of conjunctivitis, with separate consideration for the specific cause as detailed later.

Frequently, treatment is supportive. Cold compresses help alleviate the swelling and lid discomfort. Broad-spectrum antibiotic drops are used for bacterial conjunctivitis and often to prevent superinfection with other organisms. Erythromycin is appropriate for uncomplicated cases. A fluoroquinolone that provides coverage against *Pseudomonas* should be given to contact lens wearers. Topical corticosteroids should be prescribed only after consultation with an ophthalmologist and should never be used in a patient with suspected or confirmed herpes infection. Artificial tears alleviate keratitis and photophobia.
**ADENOVIRUS**

Adenovirus infection requires supportive care consisting of cool compresses, decongestants, and lubricants, as well as topical antibiotics to prevent superinfection. Because of the high transmissibility of adenovirus, care should be taken to prevent contamination of the other eye and those of others. Cases of adenovirus conjunctivitis can be managed on an outpatient basis.

**HERPES SIMPLEX CONJUNCTIVITIS**

Ophthalmologic consultation is indicated immediately for patients with herpes simplex conjunctivitis. The ophthalmologist may consider mechanical débridement. Topical antivirals such as 3% vidarabine and 1% trifluridine are prescribed in consultation with an ophthalmologist. Up to 97% of patients have been shown to heal within 2 weeks following trifluridine therapy. Topical prophylactic antibiotics and cycloplegia are also used.

**HERPES ZOSTER OPHTHALMICUS**

The EP should consult an ophthalmologist about a patient with herpes zoster ophthalmicus. Systemic antiviral agents are indicated early in the disorder. Early treatment with antiviral therapy within 72 hours of onset of the rash has been shown to reduce acute pain and ocular complications. Corticosteroid therapy may be considered in consultation with the ophthalmologist.

**UNCOMPPLICATED BACTERIAL CONJUNCTIVITIS**

Supportive care with warm compresses and lubricants should be given as needed for bacterial conjunctivitis. Topical antibiotics should be prescribed. The multiple choices include erythromycin, 10% sulfacetamide, 0.3% gentamicin, polymyxin B–neomycin-bacitracin (Neosporin), and ciprofloxacin. Use of neomycin solutions is associated with a relatively high incidence of hypersensitivity. Coverage against *Pseudomonas* should be included for contact lens wearers.

**GONOCOCCAL CONJUNCTIVITIS**

Gonococcal conjunctivitis should be considered a systemic condition. Affected patients require emergency ophthalmologic consultation, and hospital admission is usually indicated. Treatment involves topical and parenteral antibiotic therapy and frequent eye irrigation to prevent corneal perforation. In some situations, patients are given one dose of ceftriaxone intramuscularly and are then discharged after receiving topical antibiotics, instructions for eye rinsing, and arrangements for close follow-up.

**CHLAMYDIAL CONJUNCTIVITIS**

Like gonococcal infection, chlamydial conjunctivitis requires systemic therapy. Treatment involves oral and topical antibiotics. In neonates, systemic therapy is effective for concomitant pneumonia.

**FUNGAL CONJUNCTIVITIS**

For a patient with fungal conjunctivitis, the EP should consult with an ophthalmologist about prescribing an appropriate topical agent, such as a 5% suspension of natamycin. Patients with this eye disorder require close follow-up.

**ALLERGIC CONJUNCTIVITIS**

Patients with allergic conjunctivitis need supportive care with compresses, artificial tears, and ocular decongestants. Diphenhydramine therapy can also be effective.

**CORNEAL ABRASIONS**

Corneal abrasions, one of the most common ocular injuries, account for 10% of ED visits related to ocular complaints. They result from scraping away of the corneal epithelium by contact with a foreign body or application of a moving force, such as rubbing over a closed lid. Most corneal abrasions heal spontaneously without long-term sequelae; on occasion, however, scarring and permanent epithelial damage ensue. Corneal abrasions are more common in contact lens wearers.

**PATHOPHYSIOLOGY**

Corneal abrasions are defects in the corneal surface that are typically limited to the epithelial layer. Sometimes the bulbar conjunctiva is also affected. Severe injuries can involve the deeper, thicker stromal layer of the cornea.

**PRESENTING SIGNS AND SYMPTOMS**

Common complaints of patients with corneal abrasions include photophobia, foreign body sensation, pain, and tearing. Conjunctival injection and blepharospasm may or may not be seen. Depending on the location and size of the abrasion, patients may also complain of decreased visual acuity. Fluorescein examination demonstrates the abrasion as a staining defect (Fig. 26.8). If a linear abrasion is noted, the EP should search carefully for a retained foreign body on the inner side of the upper eyelid. Corneal ulceration should be excluded with a slit-lamp examination, especially in contact lens wearers. A topical anesthetic should be administered to facilitate the examination.

**TIPS AND TRICKS**

Perform a slit-lamp examination before fluorescein examination to prevent false-positive results of assessment for corneal abrasions.

Apply local anesthetic (e.g., tetracaine) to facilitate a slit-lamp examination.

A cotton-tipped applicator can be used to evert the upper eyelid.

Never send a patient home with topical anesthetic eyedrops, which can raise the risk for further injury.

**DIFFERENTIAL DIAGNOSIS**

All entities that cause eye pain should be included in the differential diagnosis for corneal abrasion. Because erythema and changes in visual acuity may or may not be present, the differential diagnosis has to be tailored to the individual case. Examination and measurement of IOP should eliminate glaucoma as a cause of the symptoms. Slit-lamp examination demonstrates cells and flare in the anterior chamber in a patient with iritis. Lack of infiltrate and ulcer morphology exclude corneal ulcers. The EP should look carefully for a foreign body to eliminate it as a cause of the complaints.
SECTION III  HEAD AND NECK DISORDERS

PERFORATION. RISK FACTORS FOR CORNEAL ULCER INCLUDE EYE TRAUMA, KNOWN INFECTION, CONTACT LENS WEAR, AND IMMUNOSUPPRESSION.

PATHOPHYSIOLOGY

Even seemingly minor trauma involving the cornea can create a break, which serves as a port of entry for bacteria. Conditions such as lack of lubrication and malnutrition make the cornea more susceptible to injury.

PRESENTING SIGNS AND SYMPTOMS

Corneal ulcers cause significant eye pain, ciliary injection, tearing, foreign body sensation, blurry vision, and photophobia. Eyelid swelling and purulent drainage may be present. Depending on the location and extent of the lesion, visual acuity may be decreased. Inspection may show eyelid swelling and erythema. Large ulcers can be seen as round or oval white spots on the cornea with the naked eye. Fluorescein and slit-lamp examinations demonstrate a corneal defect, usually with sharply demarcated borders and a gray appearance of the infiltrated ulcer base. On examination of the anterior chamber, hypopyon or a flare consistent with iritis is often seen. With the exception of the classic dendritic lesions that occur with herpes simplex virus infection, no pathognomonic signs or symptoms can be used to diagnose the cause of the ulcer seen on examination (Fig. 26.9).

DIFFERENTIAL DIAGNOSIS

The same conditions that must be considered in the differential diagnosis for patients with corneal abrasions must be considered for those with corneal ulcers.

TREATMENT AND DISPOSITION

Immediate ophthalmologic consultation should be obtained for a patient with a corneal ulcer. Some ophthalmologists advocate discharge with follow-up the next day. A cycloplegic agent such as homatropine is given for comfort. Frequent
topical antibiotic therapy should be prescribed. The typical regimen involves administration of the drops every 1 to 2 hours until the follow-up appointment the next day.

**OCULAR FOREIGN BODIES**

Corneal foreign bodies are generally superficial and do not cause long-term morbidity. However, if allowed to remain in place for a long enough time, infection, tissue necrosis, and scarring may occur.

**PATHOPHYSIOLOGY**

Objects, especially those projected with considerable force, may become embedded in the corneal epithelium or deeper into the stroma. The associated irritation triggers a cascade of events, including vascular dilation, which is manifested as conjunctival injection and lid edema.

**PRESENTING SIGNS AND SYMPTOMS**

Typical symptoms of an ocular foreign body include pain, photophobia, tearing, conjunctival injection, and a foreign body sensation. Examination may show conjunctival injection, a visible foreign body, a corneal epithelial defect, and corneal edema. White blood cell mobilization may occur and can be detected as anterior chamber flare and the presence of cells. Visual acuity can be decreased. Metallic foreign bodies can cause visible rust rings (Fig. 26.10).

**DIFFERENTIAL DIAGNOSIS**

Conditions that may mimic corneal abrasion and corneal ulceration must also be considered in patients with an ocular foreign body. Application of topical anesthesia blunts or obliterates the pain and photophobia associated with superficial corneal processes. This response can be helpful in distinguishing among the various eye disorders.

**DIAGNOSIS**

The diagnosis of an ocular foreign body is based on the history and physical findings. If there is concern about a foreign body that is not visible, especially an intraocular foreign body, a CT scan should be obtained. MRI is contraindicated if it is possible that the foreign body is metallic. Ultrascanography can be used to visualize a superficial foreign body, but this modality is limited by the type of particle, as well as possible obscuration of findings by processes such as subconjunctival hemorrhage. A Seidel test should be performed to look for corneal rupture if deep projection is suspected. The lids should be everted and a possible lodged foreign body sought.

**TREATMENT AND DISPOSITION**

Treatment consists first of removal of the foreign body. Topical anesthesia should be provided and a cycloplegic agent considered. Superficial foreign bodies are removed with a spud or needle. A cotton-tipped applicator should be used with great caution because its large surface area may result in abrasion. The foreign body should be removed under magnification with a slit lamp. The EP should approach the foreign body with the removal device held parallel to the surface of the eye to avoid inadvertent perforation. Retained rust rings after removal of a metallic foreign body must be removed with a rust ring drill; an ophthalmologist should be consulted for this maneuver.

After removal of the foreign body, the patient should be given topical antibiotics. Patching of the eye for comfort is not necessary and is strictly contraindicated in those with severe corneal injury because it may foster infection. Pain control should be adequate, and arrangements should be made for prompt follow-up.

**INTRAOCULAR FOREIGN BODY**

More than three fourths of intraocular foreign bodies enter the eye through the cornea. Suspicion of such a foreign body is based on patient complaints, as well as the history. Injuries associated with mechanical grinding, drilling, and hammering should raise the possibility of an intraocular foreign body. Intraorbital and intracranial injury should always be considered in patients with an intraocular injury.

The extent and process of the eye damage depend on the object involved and the area penetrated. Because of gravity, the inferior aspect of the eye is more commonly injured. The composition of the object involved affects local tissue reaction. Inert substances such as glass cause less reaction than organic materials do. Metallic and magnetic substances are most common.

The signs and symptoms also vary according to the factors just described. Patients often complain of discomfort or pain deep within the eye. The presence of obvious abnormalities on inspection, such as conjunctival injection, is variable. Visual acuity is also contingent on the area involved. Careful slit-lamp and funduscopic examinations should be performed to search for the object. An abnormally shaped pupil is suspicious for rupture of the globe.
CT is the imaging modality of choice if it is necessary to search for the injury or to more closely ascertain its specifics. Ultrasonography can be helpful with relatively superficial objects. Plain radiographs cannot distinguish between intraocular and extraocular positions of a foreign body. MRI cannot be used if there is any suspicion that the foreign body may be metallic.

**DIFFERENTIAL DIAGNOSIS**

If the eye with the foreign body appears normal externally, inspection alone excludes several painful eye disorders, such as iritis. Application of topical anesthetics should not affect the pain caused by an intraocular foreign body—in contrast to the pain associated with a corneal foreign body or abrasion. A careful examination can exclude glaucoma as the cause of the patient’s symptoms.

**TREATMENT**

Consultation with an ophthalmologist should be sought immediately. The patient should not eat or drink, and antibiotics and pain medications should be administered. Tetanus status should be updated as necessary. Generally, intraocular foreign bodies are removed surgically. The technique and approach are chosen by the ophthalmologist. Patients with an intraocular foreign body should be admitted to the hospital.

**OCULAR BURNS**

Ocular burns, which include burns involving the sclera, conjunctiva, cornea, and lids, can be damaging to visual integrity, as well as cosmesis. Burns may be chemical, thermal, or related to radiation exposure. The method and extent of damage vary with the cause.

**PATHOPHYSIOLOGY**

Burns cause tissue damage by denaturing and coagulating cellular proteins and by leading to vascular ischemia. Thermal burns usually cause superficial epithelial destruction, but deep penetration can occur. Radiation injury causes punctuate keratitis, which is extremely painful. Patients with radiation ocular burns report exposure to sun lamps, tanning booths, high altitudes, or welder’s arcs. Acidic burns cause coagulation necrosis, which serves as a barrier and limits the extent of penetration. Alkaline chemicals can cause devastating injury. Such a chemical causes liquefaction necrosis, which continually penetrates and dissolves tissue until the chemical is removed. At pH values greater than 11.5, the damage is generally irreversible.

**PRESENTING SIGNS AND SYMPTOMS**

Patients usually complain of eye pain and limited visual acuity. Examination in the acute phase often shows corneal cloudiness and scleral whitening. The eye may be erythematous or whitened. Findings consistent with anterior chamber reaction, chemosis, and vascular engorgement may be present. Radiation burn or ultraviolet keratitis causes intense pain, tearing, photophobia, blepharospasm, and a foreign body sensation. Physical findings include punctate lesions on the corneal epithelium, conjunctival injection, and decreased visual acuity. Thermal burns are almost always limited to the corneal epithelium.

**DIFFERENTIAL DIAGNOSIS**

A history of exposure usually leads to a clear diagnosis. Radiation burns are not always so clear-cut because symptoms develop 6 to 10 hours after exposure to the light source. Other conditions to consider are iritis, glaucoma, corneal ulcer, corneal abrasion, and a retained foreign body. Slit-lamp and fluorescein examinations allow differentiation among the various entities.

**DIAGNOSIS**

The type of chemical burn can be diagnosed by determination of the pH of the affected eye. Findings depend on the concentration of the chemical and the duration of exposure to it. Most burns can be diagnosed from the history alone. Radiation burns can be a bit more challenging to diagnose because of extreme patient discomfort. Providing adequate topical analgesia should enable examination.

**TREATMENT AND DISPOSITION**

The most important component in the treatment of chemical burns is copious irrigation. Eye irrigation should be started immediately—with no waiting even for measurement of visual acuity. After irrigation for 30 minutes, the pH should be checked. The EP should not withhold irrigation or delay its initiation even if the patient underwent prehospital irrigation. Irrigation should continue until a normal pH is recorded. Once a normal pH is obtained, the measurement should be repeated 10 to 15 minutes later to confirm neutrality. Topical anesthetics and manual lid retraction may be necessary for proper irrigation. Any particles should be removed from the fornices with a cotton swab.

After adequate irrigation, complete examination of the eye, including slit-lamp examination and determination of visual acuity, should be performed. Patients with minor burns can be discharged home with topical antibiotics, oral analgesics, and cycloplegics as necessary with arrangements for follow-up in 24 hours. An ophthalmologist should be consulted for all but the most minor ocular burns. Severe burns may cause secondary glaucoma, which is treated in consultation with the ophthalmologist. Patients with severe burns require admission for monitoring, including IOP measurements, and adequate analgesia.

Most thermal burns, which are relatively minor and restricted to the lid and corneal epithelium, can be treated the same as corneal abrasions. Initial irrigation may provide relief. Topical antibiotics, oral pain medications, and cold compresses should be provided. Patients can be discharged with outpatient follow-up. An ophthalmologist should be consulted for more severe burns.
Radiation burns are treated with cycloplegic agents and topical antibiotics. Eye patching can be considered for comfort, and oral pain medications should be prescribed. Topical anesthetics delay healing and can lead to corneal ulcer formation. Follow-up in 24 hours should be arranged.

**CHAPTER 26  EYE EMERGENCIES**

**RETROBULBAR HEMATOMA**

Retrobulbar hematoma is bleeding in the potential space surrounding the globe. It results from blunt trauma, as well as from retrobulbar injection and operative intervention. This entity can compromise vision, so immediate recognition and intervention are warranted. Bleeding typically results from injury to the infraorbital artery or one of its branches. Accumulation of blood results in an increase in pressure, which ultimately compresses blood vessels and other structures. The compression leads to optic nerve and central retinal artery ischemia. With trauma, concomitant orbital wall fractures serve to decompress the hemorrhage, thereby sparing vision.

**PRESENTING SIGNS AND SYMPTOMS**

Severe eye pain, nausea, vomiting, diplopia, and decreases in both visual acuity and eye movement are common complaints at initial evaluation of a patient with retrobulbar hematoma. Physical findings include proptosis, decreased ocular motility, visual loss, elevated IOP, and hemorrhagic chemosis. An afferent pupillary defect is common (Fig. 26.11).

**DIAGNOSIS**

Clinical examination suggests the diagnosis. If the diagnosis is in doubt, CT can be performed to demonstrate the hematoma.

**TREATMENT**

The rate of development of retrobulbar hematoma dictates the treatment. If the condition develops over minutes, the eye must be decompressed immediately via lateral canthotomy (Fig. 26.12). Orbital CT demonstrates the hematoma; however, treatment should not be delayed while waiting for imaging to be performed. If the process is slower and develops over a period of hours, conservative management can be effective and consists of head elevation, ice packs to reduce swelling, intravenous acetazolamide and mannitol, and topical beta-blockers. Progress is monitored through serial measurements of IOP and pupillary reactivity. An ophthalmologist should be notified for consultation as soon as the diagnosis is suspected. Patients with retrobulbar hematoma are admitted to the hospital to monitor progress.

**HYPHEMA**

Accumulation of blood in the anterior chamber is called hyphema. Traumatic hyphema, which can occur from both blunt and penetrating mechanisms, is generally caused by a ruptured iris root vessel. Hyphemas range from minimal blood seen only with the slit lamp to the “eight ball” or total hyphema with blood that has clotted. Spontaneous hyphemas are most commonly associated with sickle cell disease and the neovascularization of diabetes. Even small hyphemas can signal significant injury.

**PRESENTING SIGNS AND SYMPTOMS**

Patient symptoms and findings on examination correlate with the size of the hyphema. Typically, patients complain of eye
pain, decreased visual acuity, and photophobia. If the patient is upright, the hyphema usually layers out in the inferior portion of the anterior chamber. Depending on the size of the hyphema, it can be seen with either the naked eye or a slit-lamp examination. If the hyphema is large, IOP can be elevated. IOP is elevated in approximately 27% of patients. The pressure is usually mild and self-limited. Pressures greater than 35 mm Hg with durations greater than 5 to 14 days are more likely to be associated with optic atrophy.20 Generally, no afferent pupillary defect is present (Fig. 26.13).

**DIAGNOSIS**

The diagnosis is made by visualization of blood in the anterior chamber.

**TREATMENT AND DISPOSITION**

All patients with hyphemas should be seen by an ophthalmologist. The goal is to stop damage to the visual process by preventing or curbing elevations in IOP. The patient’s head should be elevated to allow inferior settling of the red blood cells. Such settling will prevent clogging of the trabecular meshwork. The pupil should be dilated to avoid “pupillary play”—movements of the iris to accommodate changing light conditions; this step should be taken in consultation with the ophthalmologist. Dilation does not block drainage of aqueous humor in normal eyes. Topical beta-blockers should be used to lower IOP. Topical carbonic anhydrase inhibitors, and systemic acetazolamide or mannitol may also be considered. Adequate analgesia should be given, with care taken to avoid aspirin and other antiplatelet agents.

Surgery may be necessary if the elevated IOP is refractory to medical therapy or to remove a large clot. Patients with hyphemas larger than 50%, decreased vision, increased IOP, and sickle cell disease should all be considered for admission.24 In consultation with an ophthalmologist it may be determined that a patient with an extremely small hyphema can receive outpatient management. The major complication of hyphema is rebleeding after 2 to 5 days when the initial clot loosens, which results in potentially severe elevations in IOP. The reported incidence of rebleeding is between 6% and 33%.20

**ORBITAL WALL OR BLOW-OUT FRACTURES**

Blunt force to the orbital region can raise intraorbital pressure, relief of which is accomplished by fracture of the orbital walls. A fracture of the orbital wall should always be suspected when a patient has soft tissue swelling following trauma to the globe. The inferior and medial walls are most frequently involved. The orbital contents slip into the corresponding sinus: the maxillary sinus for inferior wall fractures and the ethmoid sinus for medial wall fractures. Concomitant facial injuries should be sought in a patient with an orbital wall or blow-out fracture (Fig. 26.14).

**PRESENTING SIGNS AND SYMPTOMS**

The signs and symptoms in patients with an orbital wall or blow-out fracture can be highly variable and range from mild swelling and ecchymosis to impairment of vision. Patients may exhibit tenderness with palpation of the orbit. Intraorbital emphysema can often be found by examination. Inferior wall fractures can cause entrapment of the inferior rectus and inferior oblique muscles and orbital fat. Patients may have restricted upward gaze and diplopia, anesthesia of the ipsilateral cheek and upper lip, and ptosis. Epistaxis and diplopia can be seen with medial wall fractures. On rare occasion, orbital emphysema can cause a mass effect in which the optic nerve is compressed and blindness ensues.

**DIAGNOSIS**

A Waters view radiograph can show indirect signs of fracture: a cloudy sinus, a bulge extending from the orbit into the maxillary sinus (the teardrop sign), or an air-fluid level in the maxillary sinus. CT is the diagnostic study of choice because it demonstrates the fracture, as well as other injuries. The use of bedside ultrasound has also shown to be helpful in the identification of orbital wall fractures.25
CHAPTER 26  EYE EMERGENCIES

TREATMENT AND DISPOSITION

Indications for surgical repair include muscle entrapment and cosmetic deformity with significant enophthalmos. Immediate surgery is not necessary. Surgery is delayed to allow abatement of the swelling and a better examination. The preferred time frame for operative repair is 10 to 14 days, which optimizes the balance between reduced swelling and absence of scar tissue formation. Administration of prophylactic antibiotics for an orbital wall or blow-out fracture without evidence of sinus infection is controversial. Data are inadequate for a definitive recommendation, as review of 214 studies to examine this very question found.26,27

RUPTURED GLOBE

Globe rupture involves a full-thickness defect in the cornea, sclera, or both. Penetrating mechanisms are almost always involved. Rarely, enough force is generated by a blunt injury that transmission of the force results in eventual rupture. Ruptures are most common at the insertions of the intraocular muscles or at the limbus, where the sclera is thinnest.28 This entity is a true ophthalmologic emergency and always requires surgical intervention.

Sharp objects and objects traveling at considerable velocity have the potential to perforate the globe directly. Any projectile injury can cause globe rupture. Significant blunt force can result in compression of the globe with resultant increases in IOP sizable enough to tear the sclera. Such injuries typically occur where the sclera is the thinnest, such as at muscle insertion sites or sites of previous surgery.

PRESENTING SIGNS AND SYMPTOMS

Patients with globe rupture complain of eye pain and decreased visual acuity. Because this entity is associated with a high rate of concomitant orbital floor fractures, patients may report diplopia. Rupture may not be easily apparent on examination. A shallow anterior chamber on slit-lamp examination, hyphema, and an irregular (teardrop) pupil are possible findings. A Seidel test can identify wound leaks from the anterior chamber.

DIAGNOSIS

Diagnosis is not always easy. The history and physical findings described lead to the diagnosis. Though not always indicated, CT can detect occult tears, as well as retained foreign bodies. Plain radiographs may show foreign bodies.

TREATMENT AND DISPOSITION

Direct pressure should never be applied to a globe that is suspected or confirmed to be ruptured because of the risk for extrusion of intraocular contents. Although a lower than normal IOP is a good indication of rupture, tonometry should not be performed in patients with suspicion of globe rupture. A protective eye shield should be placed, and an ophthalmologist should be contacted immediately. The patient’s tetanus status should be checked and updated if necessary, and a dose of prophylactic antibiotics should be given to prevent endophthalmitis. Because skin flora is typically involved in infections of a ruptured globe, cefazolin or ciprofloxacin plus clindamycin is a good choice. Adequate antiemetics should be given to prevent Valsalva maneuvers. Surgery is performed expeditiously, and all patients with globe rupture are admitted to the hospital.

TRAUMATIC IRRITIS

Blunt ocular trauma can contuse and irritate the iris, with resultant ciliary spasm. Symptoms usually start 1 to 4 days after the injury.

PRESENTING SIGNS AND SYMPTOMS AND DIAGNOSIS

Eye pain and photophobia are the most common patient complaints with traumatic iritis. Patients report impaired vision. Evaluation shows perilimbal conjunctival injection, cells and flare in the anterior chamber, and a constricted, weakly dilating pupil.

TREATMENT AND DISPOSITION

Treatment involves administration of a long-acting cycloplegic agent such as 5% homatropine, a topical steroid chosen in consultation with an ophthalmologist, and oral analgesics. Patients can be discharged with arrangements for ophthalmologic follow-up.

Ear Emergencies

Thomas Morrissey and John B. Lissoway

KEY POINTS

- Ears are exquisitely sensitive organs. Treating pain is important in caring for patients with ear problems and will facilitate performance of the examination.
- Simple otitis externa can be treated with topical medications and débridement.
- Many cases of uncomplicated otitis media resolve spontaneously. Watchful waiting with use of a “rescue” antibiotic prescription has been shown to decrease unnecessary antibiotic use and improve patient and parent satisfaction.
- Subtle malalignments or malformations after repair of ear trauma can have profound cosmetic consequences.
- Pain from the teeth, pharynx, or temporomandibular joint or from cranial or cervical neuropathies can be referred to the ear.
- Hearing loss must be categorized as conductive or sensorineural. Conductive lesions can often be diagnosed clinically. Sensorineural hearing loss requires urgent referral to an otolaryngologist to improve the chance for recovery of hearing.

PATHOPHYSIOLOGY

Anatomically, the ear is divided into three areas. The external ear extends outward from the tympanic membrane and serves to guide sound waves into the “business end” of the ear. Its external location places it at high risk for traumatic injuries, environmental exposure, obstruction, and infection. The middle ear extends inward from the tympanic membrane to the oval and round windows. It transfers mechanical energy from the outside world, through the ossicles in the middle ear, to the inner ear, where it is translated into signals that the brain interprets as sound. The enclosed nature of the middle ear predisposes it to accumulation of fluid, infection, and barotrauma. The inner ear is composed of the structures responsible for sound transduction and balance (organ of Corti, cochlea, vestibule [saccule and utricle], and semicircular canals). Dysfunction of this portion of the ear accounts for some visits to the emergency department (ED), but treatment options are limited and consist mostly of patient education, prognostication, limitation of further damage, and appropriate ear, nose, and throat (ENT) referral. The ear is surrounded by the middle cranial fossa superiorly, the mastoid air cells posteriorly, the cranial vault medially, and the temporomandibular joint and parotid glands anteriorly. Evaluation of these structures is a necessary part of the ear examination.

EAR PAIN

Ear pain may be referred from or occur as a result of infections, trauma, or a foreign body affecting the ear.

INFECTIONS

Ear pain is commonly caused by infection. Any portion of the ear can become infected. The disease state is categorized by the portion of the ear that is primarily affected.

Otitis Externa

Infections of the outer ear canal most often begin when breakdown of the natural barriers allow infectious organisms to gain a foothold. This commonly occurs in the summer months, when warm weather and frequent water sports lead to excessive ear moisture, which washes out the cerumen and alkalinizes the normally acidic environment—hence the term swimmer’s ear. Cotton swab trauma can be the inciting event, especially in diabetic patients.

The most common pathogens are Pseudomonas aeruginosa (frequently found in pools) and Staphylococcus aureus. Less common causes include chemical or contact dermatitis and fungal infections. The spectrum of disease ranges from mild (with minimal pain and inflammation of the canal) to severe (complete canal occlusion and exquisite pain). Further extension results in an invasive or systemic disease state called necrotizing external otitis (formerly malignant otitis externa; see later).

The diagnosis of external otitis is made from the history and findings of pain, pruritus, canal irritation, and edema on physical examination. Thick greenish discharge suggests Pseudomonas, whereas golden crusting implicates S. aureus. Other colored or black discharge may indicate fungal infections, of which Candida and Aspergillus are the most commonly isolated species. Small abscesses in the external ear canal can cause obstruction. These abscesses often require incision and drainage, as well as standard treatment of otitis externa.
Treatment

Treatment consists of débridement or aural toilet and antibiotics. Despite a relative lack of controlled studies, the American Academy of Otolaryngology—Head and Neck Surgery Foundation has released clinical practice guidelines based on evidence available as of 2005 (Fig. 27.1; also see the Patient Teaching Tips box). Briefly, these guidelines are as follows:

1. Distinguish acute external otitis from other causes of otalgia, otorrhea, and inflammation. Diagnostic criteria include rapid onset (2 to 3 days) and a duration of less than 3 weeks. Symptoms include otalgia, itching, or fullness. Signs include tenderness of the pinna or tragus or visual evidence of canal erythema, edema, or otorrhea.
2. Assess for factors that may complicate the disease or treatment (e.g., perforation of the tympanic membrane or eustachian tubes, immunocompromising states, previous radiotherapy). These factors raise the level of treatment needed and heighten suspicion for more invasive disease states such as necrotizing otitis externa (see later). These guidelines pertain to patients older than 2 years with normal states of health.
3. Pay attention to assessment and treatment of pain! Mild to moderate pain usually responds to acetaminophen or a nonsteroidal antiinflammatory drug alone or in combination with an opioid.
4. Topical preparations are first-line agents for the treatment of acute uncomplicated otitis externa. Reserve systemic therapy for immunocompromised patients or extension of disease beyond the ear canal. Topical therapy produces drug concentrations 100 to 1000 times that available with systemic administration and can thus overwhelm resistance mechanisms. No clear evidence points to the superiority of one particular treatment. Antiseptic and acidifying agents (e.g., aluminum acetate and boric acid) appear to work as well as antibiotic-containing solutions (e.g., solutions that contain cortisone and Neosporin or a fluoroquinolone). Corticosteroids in the drops decrease the duration of pain by approximately 1 day.
5. Make sure that the patient can instill the drops correctly. Edema can prevent the drops from entering the canal. Debris or detritus should be removed or irrigated out. Placement of a compressed cellulose or ribbon gauze wick in the canal will enable the drops to penetrate, but placement can be painful. Within 1 to 2 days the canal edema should subside, and the wick falls out or can be removed (Fig. 27.2).
6. If you cannot be sure that the tympanic membrane is intact, use a nonototoxic, pH-balanced preparation such as ofloxacin and ciprofloxacin-dexamethasone.
7. Educate and reassess your patients. Pain should decrease significantly in 1 to 2 days and resolve by 4 to 7 days. Failure to improve may indicate more invasive disease (e.g., necrotizing otitis), inability of drops to reach the canal (wick needed), or noncompliance with therapy.

Fig. 27.1 Algorithm for the treatment of acute otitis externa. TM, Tympanic membrane. (Adapted from Rosenfeld RM, Brown L, Cannon CR, et al. Clinical practice guideline: acute otitis externa. Otolaryngol Head Neck Surg 2006;134:S4-23.)
Acute otitis media is primarily a disease of children. In early childhood the eustachian tubes are not angled downward and do not drain well spontaneously. The relatively small tube size and higher frequency of URIs in children 6 to 24 months old lead to the highest incidence of otitis media in this age group. Another increase in the incidence of otitis media occurs at 5 to 6 years, which coincides with entrance into school and a higher frequency of URIs. The craniofacial abnormalities seen with some developmental disorders (e.g., Down syndrome) also predispose to the development of middle ear effusions.

Otitis media is one of the most common reasons for pediatric physician visits, with estimates that $5 billion is spent as direct or indirect costs annually. A significant proportion of cases are probably misdiagnosed, and guidelines have been issued to ensure proper diagnosis and thus curb wasting of resources.8 "Visualization of the tympanic membrane with identification of a middle ear effusion and inflammatory changes is necessary to establish the diagnosis with certainty."8 Effusions are signified on physical examination by bulging of the tympanic membrane, bubbles or fluid levels behind the membrane, loss of the light reflex (opacification or cloudiness of the membrane), and (most definitively) loss of tympanic membrane mobility on pneumatic insufflation.

Newer modalities, such as acoustic reflectometry and tympanometry, also demonstrate middle ear effusions but are not available in many EDs. Tympanic membrane injection (common in crying children) or the presence of fluid alone is not enough to make the diagnosis of AOM. Accompanying fever, pain, purulent drainage, or other systemic signs point to acute infection.

Chronic otitis media is defined as (1) the chronic presence of middle ear effusion in the absence of acute signs of infection or (2) chronic complications from otitis media, including persistent perforation of the tympanic membrane.

The role of infectious organisms in chronic otitis media is unclear. It was originally thought to be a noninfectious entity, but studies have shown the presence of bacteria (and bacterial DNA, mRNA, and proteins) in a biofilm model of chronic otitis
media. Current guidelines offer the option of a trial of antibiotics (typically amoxicillin) or watchful waiting as treatment.3

Treatment
American physicians have historically treated otitis media with antibiotics, whereas European physicians are typically less likely to do so. A 2005 study compared immediate antibiotic treatment with watchful waiting for nonsevere otitis media.10 In the watchful waiting group, 66% of children had complete resolution of symptoms with no antibiotic treatment, no adverse outcomes, cost savings, and similar patient satisfaction.

Treatment options and recommendations by the American Academy of Pediatrics for acute otitis media include the following4:

1. Pain management must be addressed in patients with AOM. Particular attention should be paid to pain management in the first 24 hours of any treatment regimen.
2. Observation without the use of antibacterial agents is an option for the first 2 to 3 days in selected children11 (Table 27.1). The child must be otherwise healthy and in a sound social environment with an adult capable of watching the child closely and returning to the physician if the condition deteriorates.
3. If antimicrobial treatment is chosen, the first-line agent should be amoxicillin, 80 to 90 mg/kg/day. With treatment failures or cases in which broader β-lactamase coverage is desired, amoxicillin, 90 mg/kg, with clavulanate, 6.4 mg/kg, in two divided doses can be used. Penicillin-allergic patients (non-type 1) can be treated with a third-generation cephalosporin (cefdinir, cefpodoxime, cefuroxime, or ceftriaxone). For patients with severe type 1 penicillin allergy, alternative treatments include azithromycin, clarithromycin, erythromycin-sulfisoxazole, and sulfamethoxazole-trimethoprim. Treatment is aimed at common pathogens, including S. pneumoniae, nontypeable H. influenzae, and M. catarrhalis. Mycoplasma species can also cause otitis media and are often responsible for blister formation on the tympanic membrane (bullous myringitis). Multiple virus species can cause otitis media and are obviously unaffected by antibiotics.
4. Failure of response in 2 to 3 days should prompt initiation of or a change in antibiotic treatment. If amoxicillin fails, alternatives include amoxicillin-clavulanate, cephalosporin (ceftriaxone), macrolides, and sulfa preparations.

Some authorities have suggested a compromise between meeting patients’ expectations and decreasing the inappropriate overuse of antibiotics.12,13 Patients can be given a “rescue” prescription, which they should have filled only if no improvement occurs in 2 to 3 days.

Chronic otitis media is not typically an emergency. The American Academies of Family Physicians, Pediatrics, and Otolaryngology–Head and Neck Surgeons have recently issued guidelines to direct the diagnosis and treatment of otitis media with effusion; they are summarized as follows:

1. Pneumatic otoscopy should be used to identify the presence of effusion.
2. The history and physical examination (to search for acute signs and symptoms of inflammation or infection) should be used to distinguish this disorder from AOM.
3. Otitis media with effusion should be managed with watchful waiting for 3 months in children who are not at risk for speech, hearing, or learning disabilities.
4. Hearing tests (referral to an otolaryngologist) should be performed if the disease lasts longer than 3 months or earlier if any language, learning, or hearing problems are suspected.
5. Antihistamines and decongestants are ineffective and should not be used as treatment; antimicrobial agents and steroids do not have long-term efficacy and should not be used for routine management.

Middle ear effusions in adults should be able to be explained clinically (e.g., after URI) and should resolve within a few weeks. Any other circumstances require otolaryngologic

PATIENT TEACHING TIPS

Otitis Media
Most patients with otitis media can be treated as outpatients.

If antibiotic therapy is chosen, patients should be counseled to take the entire course of antibiotic therapy.

Watchful waiting with a rescue prescription can be chosen for healthy-appearing patients older than 2 years. Parents should be educated about signs of worsening infection, including pain and fever.

Patients should follow up with their primary physicians or return to the emergency department if no improvement occurs in 1 to 3 days.

Patients should be warned of the signs and symptoms of intratemporal and intracranial complications (headache, neck stiffness, vomiting, altered mental status).

Patients should also be apprised of the risks associated with otitis media with effusion and must be sure to follow up with their primary physicians to alleviate the risk for hearing deficits.
referral to evaluate for other nasopharyngeal disease, such as an obstructing tumor.

**Necrotizing (Malignant) Otitis Externa**

Necrotizing otitis externa (formerly known as malignant otitis externa) is aggressive extension of infection from the auditory canal to the skull base and other nearby bony structures. This complication occurs nearly exclusively in immunocompromised hosts, with elderly diabetic patients accounting for most of the affected population. It can be the initial complaint in patients with undiagnosed diabetes, and all patients with progressive ear infection need prompt evaluation for diabetes. The emergence of widespread human immunodeficiency virus infection now puts children at risk for a condition that was once almost exclusively an adult disease.14

Necrotizing otitis externa may be difficult to distinguish from simple otitis externa in the early stages, but exquisite otalgia and ototrauma unresponsive to topical measures point to the former diagnosis. The pain often extends to the temporomandibular joint and gets worse with chewing. Granulation tissue is frequently seen at the inferior portion of the canal where the cartilage and bone meet, at the site of the fissures of Santorini. Inflammation of bony structures as a result of the osteomyelitis can cause nerve palsies (facial nerve most frequently involved). Progression of the infection inward can lead to catastrophic complications such as brain or epidural abscess, sinus thrombophlebitis, and meningitis. Evaluation with computed tomography (CT) or magnetic resonance imaging (MRI) can show the extent of the invasive process and may be helpful in evaluating for intracranial complications, but arranging for such an evaluation should not delay initiation of treatment.

More than 95% of cases of necrotizing otitis externa are caused by *P. aeruginosa*, and antibiotic therapy should be aimed at this organism. Since the introduction of semisynthetic penicillins, antipseudomonal cephalosporins, and antipseudomonal fluoroquinolones, mortality from this disorder has decreased from 50% to 10%. Empiric treatment with antipseudomonal penicillins, antipseudomonal cephalosporins, and antipseudomonal fluoroquinolones, mortality from this disorder has decreased from 50% to 10%. Empiric treatment with antipseudomonal penicillins, antipseudomonal cephalosporins, and antipseudomonal fluoroquinolones, mortality from this disorder has decreased from 50% to 10%. **Mastoiditis**

All cases of otitis media are accompanied by some subclinical fluid collection in the mastoid air cells, often seen on CT. Further blockage of the communicating spaces by mucosal edema and inflammation generates pus under pressure in the mastoid air spaces and results in what we know as clinically significant mastoiditis. Left untreated, the chronic inflammation results in abscess formation and resorption of trabecular bone.

This process can further extend outward or inward. Outward extension leads to subperiosteal abscess formation. This development is associated with the classic findings for mastoiditis: tenderness and erythema over the mastoid process, outward bulging of the pinna, loss of the postauricular crease, and fluctuance behind the ear. Inward extension leads to potentially catastrophic complications such as erosion into the cranial vault, meningitis, and brain abscess formation.

Mastoiditis is a clinical diagnosis, and physical findings should prompt CT evaluation to delineate the extent of the process. Treatment consists of supportive care and resuscitation, administration of antibiotics, and otolaryngologic or ENT consultation for surgical drainage. Antibiotic coverage should initially be broad spectrum and include coverage against common otitis media pathogens, anaerobes, and *Pseudomonas* and *Bacteroides* species.

**TRAUMA**

External ear trauma can be classified into contusions and ecchymoses; seromas and hematomas; and lacerations, tears, and avulsions. Fluid collections and anatomic disruptions require directed attention because of the propensity for necrosis or disfigurement if managed inappropriately.

Blunt trauma can cause blood to collect in the fascial plane between the cartilage and the perichondrium. The cartilage is an avascular structure that derives its nutritional support from the blood supply of the perichondrium, and separation of the two starves the cartilage. Furthermore, neocartilage formation in the fluid collection space leads to scarring and deformation (cauliflower ear). Fluid collections can
be drained by either needle aspiration or open evacuation. For cosmetic purposes, collections that form lateral (external) to the cartilage layer can be drained through a medial approach. A gentle compression dressing can then be applied by packing the ear canal with dry cotton and packing the rest of the auricle with a conforming material (gauze or foam). A gauze roll and an elastic bandage can then be carefully wrapped around the head to compress the entire bandage in place while avoiding overly tight placement, which could cause ear necrosis. Follow-up within 24 hours is needed to check for reaccumulation of fluid, which would need to be redrained.

Lacerations and avulsions need special repair techniques because of the cosmetic importance of ears. As with all facial wound repairs, minimal débridement (to minimize tissue loss) and alignment of visually eye-catching anatomic lines are key to aesthetic repair. Through-and-through lacerations of the pinna necessitate alignment and repair of the underlying cartilage. The use of deep sutures should be minimized (usually one or two), and small absorbable sutures should generally be used. The overlying skin can then be closed to realign the pinna rim first, followed by closure of the remainder of the defect. Similar technique should be used for earlobe clefts, which commonly occur after abrupt traction on earrings causes either a partial or complete tear of the earlobe. Compression packing should be applied to prevent reaccumulation of fluid. Complex disruptions with significant tissue loss can be managed conservatively, with referral for plastic or reconstructive repair at a later date to maximize the chance for a good cosmetic outcome.

Direct visualization of any foreign body in an ear is critical to identification of the object and aids in the choice of removal method. A small amount of lidocaine or mineral oil instilled into the ear anesthetizes or immobilizes most insects in the ear canal within about a minute.

Methods of foreign body removal are as follows:

- **Irrigation**: An intravenous catheter without a needle (18 to 20 gauge) can be used with a 10- to 20-mL syringe. Irrigating the superior portion of the canal seems to provide the best results. The force generated is well below that needed to perforate a normal tympanic membrane. Materials that swell when wet (vegetables, cellulose, wood) should not be removed by this method because of the risk for further swelling.

- **Forceps**: Small forceps (alligator forceps) can be used to grasp objects. Use of an ENT scope and speculum greatly facilitates the process (Fig. 27.3).

- **Cyanoacrylate**: A small amount of cyanoacrylate (e.g., Super Glue) can be applied to the blunt end of a cotton-tipped applicator and held against the impacted object for about 60 seconds to glue the foreign body to the applicator and allow gentle removal of it. This method should not be attempted in a moving, uncooperative patient.

- **Right-angle probe**: A small probe can sometimes be worked behind the object and used to pull it forward. This works best for loose or pliable objects.

### Fig. 27.3
An ear, nose, and throat scope (A) frees up both hands for removal of foreign bodies. A selection of different-sized reflective speculums and forceps (B) greatly facilitates extraction of foreign bodies (bug; C).
sensorineural component refers to transduction of sound waves to electrical (neural) impulses and delivery of these impulses to the brain, where they can be interpreted as sound. Hearing can be impaired by dysfunction in either or both of these pathways. The first step in evaluating hearing complaints (and the primary guide to treatment) is to ascertain the location and extent of the hearing loss. The history and physical examination provide nearly all the information needed to guide ED treatment of hearing loss. The history must include details about the timing of hearing loss, laterality, previous episodes, associated symptoms (tinnitus, vertigo, or pain), preceding events (diving, plane rides, trauma), potential placement of a foreign body, environmental noise exposure, and potential ototoxic drugs.

Tuning fork tests provide the best clues to distinguish between conductive and sensorineural hearing loss. The key component of the test is to compare how well the ear hears conduction through bone versus conduction through air. A 512-Hz fork should be used. The Weber test compares the two ears with each other (Fig. 27.4). A vibrating fork is placed midline on the top of the head or between the front top teeth (some patients find this intolerable). The patient is asked which ear hears the vibrations better. Because outside sounds (from air conduction) suppress the perception of vibratory conduction, an ear with a conductive hearing defect will “hear” the fork vibrating through bone “louder” than the other ear will. So if the fork is heard louder in one ear, either that ear has a conductive deficit or the other ear has a neural deficit (Table 27.2).

**Sudden Hearing Loss**

Anatomically and physiologically, the hearing process consists of two parts. Conduction refers to the mechanical transmission of sound waves from the external environment through the outer and middle ear to the round window. The...

ASA, Acetylsalicylic acid; BP, blood pressure; CNS, central nervous system; CSF, cerebrospinal fluid; CVA, cerebrovascular accident; ENT, ear, nose, and throat; SNHL, sensorineural hearing loss; TM, tympanic membrane; URI, upper respiratory infection.
Sensorineural hearing loss may stem from several causes, but there are few emergency treatment options. The patient can be counseled about the variable recovery rate, and some prognosis may be given on the basis of the suspected cause of the lesion. Viral causes and inflammatory or autoimmune causes may respond to steroid treatment started in the first few days. Steroids have been regarded as standard therapy for sensorineural hearing loss suspected to be of viral etiology, although no controlled trials have shown significant benefit.\(^{21,22}\) Steroids should be prescribed with caution, and care must be taken to rule out infections, which may worsen with steroid treatment. Steroids should be given only if prompt follow-up is ensured. Antiviral agents (acyclovir, famciclovir, valacyclovir) are also commonly prescribed because of the possible role of herpes simplex virus type 1 as an etiologic agent in sensorineural hearing loss. No clear evidence has, however, shown a better outcome with steroids plus antiviral agents than with steroids alone.\(^{23-25}\)

Patients with suspected perilymph fistulas need absolute bed rest with head elevation to avoid raising intracranial pressure (and increasing flow of cerebrospinal fluid through the fistula). Some patients may require admission and sedation for this goal to be achieved.

Other causes of sensorineural hearing loss are not likely to be identified in the ED. These cases need expedited follow-up with an otolaryngologist for MRI and audiometry. Many patients receive relief from reassurance that their hearing loss is not a life-threatening event, but the emergency practitioner should be cautious and not give an overly optimistic picture because hearing often does not return after this type of hearing loss.

REFERENCES

The incidence of dental complaints in emergency departments (EDs) appears to be rising, which may reflect the increasing use of EDs as primary care facilities. Injuries involving the dentition, but adult dentoalveolar injuries are frequently associated with fractures of the mandible and face. Patients who have fractures of both the mandibular condyle and body are more likely to have related tooth injury than are patients with either isolated body or condylar fractures.

The muscles of mastication are responsible for opening and closing the mouth and are those most frequently associated with temporomandibular disorders (TMDs). The clinician should be knowledgeable about the position of the muscles to perform an examination properly and to recognize the origin of certain painful conditions. The muscles that close the mouth are those most often associated with TMDs; these muscles are the masseter, the temporalis, and the medial pterygoid (Fig. 28.1). Contraction of this group of muscles bilaterally serves to move the condyle superiorly and posteriorly, which causes the mouth to close. The muscles that open the mouth are the anterior digastric, posterior digastric, mylohyoid, geniohyoid, and infrahyoid muscles (Fig. 28.2). The lateral pterygoid muscles are responsible for anterior translation and lateral movement of the mandible (Fig. 28.3). Unilateral contraction causes lateral movement away from the side of the muscle contraction, whereas bilateral contraction causes protrusion of the mandible.

Each side of the mandible consists of the horizontal body and ascending ramus, which are connected by the angle. The bodies of the mandible are connected by the symphysis in the midline. The ascending ramus gives rise to two processes superiorly, the condylar process and the coronoid process (Fig. 28.4). The mandibular condyle, along with the mandibular fossa and the articular eminence of the temporal bone, make up the temporomandibular joint (TMJ). The TMJ provides both hinge and gliding actions. Between the mandibular condyle and the articular eminence lies the meniscus, a fibrous collagen disk. A ligamentous joint capsule surrounds the TMJ and serves to limit condylar movement. TMJ pain may be caused by a number of conditions, both traumatic and nontraumatic.

**TEETH**

**Names**

The adult dentition normally consists of 32 teeth, of which 8 are incisors, 4 are canines, 8 are premolars, and 12 are molars.
CHAPTER 28  DENTAL EMERGENCIES

From the midline to the back of the mouth on each side are a central incisor, a lateral incisor, a canine (eye tooth), two premolars, and three molars, the last of which is the troublesome wisdom tooth (Fig. 28.5).

**Numbers**
The adult teeth are numbered sequentially from 1 to 32, with the No. 1 tooth being the right upper wisdom tooth and the No. 16 tooth being the left upper wisdom tooth. The left lower wisdom tooth is No. 17, and the right lower wisdom tooth is No. 32.

**Identification of Teeth**
Numerous classification and numbering systems of the teeth have been devised; however, it is probably best for emergency practitioners (EPs) to simply describe the location and type of tooth in question, for example, “the upper (or maxillary) right second premolar” or “the left lower (or mandibular) canine.” This approach removes any question when the EP is discussing a case with a consultant.

The primary teeth, or “baby teeth,” are also best described by determining which tooth is involved, not by its official classification. A full complement of primary teeth consists of 20 teeth: 8 incisors, 4 canines, and 8 molars. The earliest
Palatal: Toward the palate; the oral surface of the maxillary teeth.
Approximal/interproximal: The contacting surfaces between two adjacent teeth.
Mesial: The interproximal surface facing anteriorly or closest to the midline.
Distal: The interproximal surface facing posteriorly or away from the midline.
Occlusal: Biting or chewing surface of the premolars and molars.
Incisal: Biting or chewing surface of the incisors and canines.
Apical: Toward the tip of the root of the tooth.
Coronal: Toward the crown or the biting surface of the tooth.

THE PERIODONTIUM
The periodontium is the attachment apparatus. It consists of the gingival and periodontal subunits, which maintain the integrity of the entire dentoalveolar unit. The gingival subunit consists of gingival tissue and junctional epithelium. The periodontal subunit consists of the periodontal ligament, the alveolar bone, and the cementum of the root of the tooth (see Fig. 28.6). The gingival sulcus is the space between the attached gingiva and the tooth. The mucobuccal fold is that area of mucosa where the attached gingiva gives rise to the looser buccal mucosa. The mucobuccal fold is the area penetrated when most dental nerve blocks are performed.
PRESENTING SIGNS AND SYMPTOMS

The patient’s signs and symptoms can be elicited by means of a thorough history. If the patient has sustained trauma, it is important to ascertain the following information:

1. When did the incident occur? This is important in the evaluation of avulsed permanent teeth because the decision to reimplant a tooth is based largely on the duration of the avulsion.
2. Were any teeth found at the scene?
3. Did the patient have any symptoms suggestive of tooth aspiration, such as coughing or choking at the scene?
4. Has the patient been using alcohol or any other sedatives or recreational drugs that may have made aspiration more likely?
5. Does the patient have amnesia, which may suggest loss of consciousness?
6. Does the patient complain of pain? Do the teeth feel as though they are touching normally? Is the pain associated with occlusion? Mandibular fractures typically worsen with jaw movement, and patients complain that their bite is off. Pain from TMJ injuries is often referred to the ear. Fractured teeth frequently hurt more with the inspiration of air or contact with cold substances.
Luxated or subluxated teeth hurt during mastication or chewing.

7. Did the patient take any over-the-counter analgesics or apply any substances to decrease the pain? Over-the-counter topical anesthetics can cause sterile abscesses when applied directly to the pulp.  

8. Is the tooth a permanent or a primary tooth? Avulsed primary teeth are managed differently from avulsed permanent teeth.

9. Does the patient have a history of bleeding disorders or allergies?

Additional historical information must be obtained if the complaint does not involve trauma:

1. Has the patient had any recent dental work? Dry sockets, for example, occur several days after a tooth has been extracted.

2. Does the patient have a history of poor dentition or multiple caries?

3. Is the patient having difficulty opening the mouth, which suggests a TMJ problem?

4. Has the patient had any difficulty swallowing? Has a change in voice or any shortness of breath occurred? Has any swelling developed? These symptoms suggest a possible deep space infection or hematoma.

5. Is the patient immunocompromised? Deep space infections spread rapidly to the mediastinum and cavernous sinus in an immunocompromised patient.

6. Does the patient have a coagulopathy secondary to aspirin, warfarin, or other anticoagulants or symptoms or a history suggestive of a bleeding disorder?

7. Was the time course of the problem insidious or rapid? Has the patient had symptoms of infection, such as fever, chills, or vomiting?

8. Does the patient have a history of rheumatic fever or valvular disease, such as mitral valve prolapse? Does the patient have artificial joints, valves, or shunts? These may predispose to endocarditis or infection of the implant or shunt if dental infection is present.

**DIFFERENTIAL DIAGNOSIS**

Trauma to the teeth usually consists of fracture, subluxation (loose but nondisplaced tooth), luxation (loose displaced tooth), intrusion, or complete avulsion. Lacerations of the oral soft tissues can be challenging to find, and therefore good lighting is essential. Trauma to the surrounding maxillofacial structures and mandible must also be considered. The final diagnosis is determined primarily by a meticulous physical examination, with radiography sometimes serving a confirmatory role.

Nontraumatic dental emergencies usually result from poor oral hygiene, recent dental instrumentation, or infection. Uncomplicated tooth pain (odontalgia) is often pulpitis, and further diagnostic testing is not necessary in the ED. The other consideration is periodontal or pulpal infection or abscess. Nonodontogenic sources may cause referred pain to the dentition. Referred pain from the sinuses or the TMJ must also be considered, especially for pain that cannot be localized (Table 28.2). A patient who has recently undergone dental instrumentation or extraction may be seen in the ED with dry socket, hematoma, or hemorrhage.

**INTERVENTIONS AND PROCEDURES**

**PHYSICAL EXAMINATION**

Simple observation and discussion with the patient can often provide clues to the diagnosis. The EP should pay attention to changes in voice, muffling, drooling, and other signs of airway
involvement. External inspection may disclose injuries such as mandibular dislocations and fractures, which often result in asymmetry, swelling, or deformity of the face. Abscesses or deep space infections will cause swelling over the involved space, although such swelling can be subtle; therefore, the face should be viewed from multiple angles. Opening of the mouth should be smooth and complete, with no limitations or hesitations. Erythema, warmth, or drainage is indicative of possible abscess, cellulitis, or hematoma formation. The face should be palpated for fractures, tenderness, and crepitus. The entire mandible and midface should be palpated with particular attention to the maxilla, zygomas, mandibular condyles, and coronoid processes. The TMJ should be palpated throughout its range of motion. No clicks, pops, or pain should occur as the joint moves.

During palpation of the anterior portion of the neck, particular attention should be paid to the area along and beneath the length of the mandibular body. The oral cavity should be examined for any bleeding, swelling, tenderness, fractures, abrasions, or lacerations, and each tooth should be percussed and accounted for. A tongue blade should be used to assess the entire mucobuccal fold region. The EP should palpate the cheek and the floor of the mouth with the thumb of a gloved hand inside the patient’s oral cavity. Each tooth should be percussed with a tongue blade for sensitivity and palpated with gloved fingers for mobility. Blood in the gingival crevice (the area where the gingiva meets the enamel) suggests a traumatized tooth or a fractured jaw (see Fig. 28.13, B). The teeth should meet symmetrically and evenly during biting, and the patient should be able to exert firm pressure on a tongue blade when biting with the molars. An inability to crack a tongue blade bilaterally when it is twisted between the molars (the tongue blade test) suggests a mandibular fracture (Fig. 28.7).

**CONTROL OF HEMORRHAGE**

Bleeding from the oral cavity is common and often associated with trauma and dental procedures. The EP is frequently the first clinician to see the problem when it occurs in a delayed manner. First, the EP should ascertain whether the bleeding is from recent dental instrumentation or was spontaneous. Spontaneous bleeding from the oral cavity that is not secondary to recent instrumentation or trauma suggests advanced periodontal disease or a systemic process.

Bleeding from the gingiva after scaling or other routine dental procedures can usually be controlled with direct pressure. Gingival bleeding that persists suggests a coagulopathy, alcoholism, medications, and other causes. Much more common than gingival bleeding is postextraction bleeding, usually from the molars. Patients with such problems usually arrive at the ED after normal office hours and after they have failed to stop the bleeding at home. The EP has a number of options to stop the bleeding. A systematic approach should be taken, as follows:

1. **Apply direct pressure.** Any excessive clot should be removed and the area anesthetized with local infiltration of lidocaine or bupivacaine with epinephrine. The epinephrine provides vasoconstriction, and the anesthetic enables the patient to bite harder. Anesthetic without epinephrine should generally be avoided because the amide anesthetics are vasodilators and may increase the bleeding. Next, insert dental roll gauze or a dental tampon into the space that was left by the extracted tooth. Dental roll gauze fits nicely into the extraction space and thus helps increase direct pressure.

2. **If the bleeding persists, insert a hemostatic agent (Celox, HemCon, Surgicel, Gelfoam) into the socket.** Both of the chitin-derived dressings (Celox, HemCon) have been shown to decrease bleeding better than direct pressure does, as well as to control bleeding in patients taking anticoagulants. If Gelfoam or Surgicel is used, the surrounding cusp of gingiva may require closure with a fast-absorbing suture to ensure that the dressing remains seated. Instruct the patient to bite down on gauze placed over the dressing. If HemCon or Celox is used or if not enough gingival tissue is available for closure, simply place the coagulating agent into the socket and have the patient bite down into gauze placed over the bleeding socket.

3. **Topical thrombin, which can usually be obtained from the operating room, is also very effective in stopping oozing blood, but it is very expensive.** Simply spraying topical thrombin onto the site and then having the patient bite into gauze generally work well.

4. **Low-temperature cautery is also very effective, although it can be destructive to tissue if not used carefully. Battery-operated thermal cautery units, which are often used for nail trephination, are available in many EDs. Anesthetize the gingiva before using the cautery.**

5. **If the preceding measures are not effective in controlling bleeding, call a specialist.** It is also reasonable to consider the use of fresh frozen plasma or platelets if a coagulopathy is determined to be present.

If the bleeding can be controlled, the patient may be discharged and instructed to not eat or drink anything for several hours and then to have only cold liquids and soft foods.

**MANAGEMENT OF PAIN**

Severe tooth pain (odontalgia), as anyone who has experienced it knows, can be debilitating. Frequently, the quickest
relief is found in the ED. The ability to perform dental nerve blocks is valuable and rewarding.

The use of bupivacaine in dental block anesthesia affords the patient the luxury of 8 to 12 hours of relative comfort until follow-up with a dentist is possible. Likewise, the use of narcotics is minimized because the patient’s pain has been relieved. Topical anesthesia in the form of 20% benzocaine or 5% lidocaine is also a valuable aid because both agents decrease the pain of intraoral injection. It behooves the EP to be able to use them properly.5

**DIAGNOSTIC TESTING**

A panoramic facial radiograph (Panorex) and a Towne view are probably the most useful and cost-effective radiographs for evaluating mandibular trauma in the ED.6 A panoramic radiograph of the mandible shows the mandible in its entirety and demonstrates fractures in all regions, including the symphysis.5 Occasionally, however, such a radiograph can miss overriding anterior fractures; if these fractures are probably present, computed tomography (CT) is indicated. The Towne view allows better visualization of the condyles than a panoramic radiograph does. A coronal CT scan is more definitive and is often used for preoperative evaluation, but it is seldom necessary for the diagnosis of isolated mandibular trauma. CT should be performed if multiple facial fractures are suspected or if the initial radiographic findings for the mandible are equivocal and clinical suspicion is high.6,7 If the patient is immobilized, mandibular films or CT scanning may be obtained. Mandibular films may miss the symphysis, and if the clinician is concerned about a symphyseal fracture, either occlusal films or a CT scan should be obtained.

Dental abscesses or infections are best treated by antibiotics, incision and drainage, or both. Although panoramic radiographic views can visualize sizable periapical abscesses, their routine use in the ED is not warranted because their results would not change the treatment and disposition of the patient.3 Bite-wing radiographs, obtained in the dentist office, are the standard for diagnosing small periapical abscesses and caries. Deep space infections of the head and neck are often difficult to localize by physical examination, and CT scanning has become the modality of choice to delineate collections of abscess or cellulitis of the face and neck.8

**TREATMENT AND DISPOSITION**

**TRAUMA**

**Fractured Teeth**

Injury to the maxillary central incisors accounts for between 70% and 80% of all tooth fractures. The morbidity associated with dental fractures can be significant and includes failure to erupt, abscess formation, loss of space in the dental arch, change in color of the tooth, ankylosis, and root resorption. The following principles apply to the ED evaluation and management of dental trauma:

1. Identify all fracture fragments and mobile teeth, and note whether a mandibular fracture is open or closed. Radiographs should be taken if fragments have intruded into the mucosa or alveolar bone. Perform chest radiography if there is any concern about aspiration of a tooth or tooth fragment.

2. The dentition is much more easily manipulated if the patient is not in significant discomfort. Tooth infiltration and dental block anesthesia should be part of the EP’s armamentarium. Narcotic and nonnarcotic alternatives, though helpful after treatment is completed, do not usually offer the patient enough comfort to allow the performance of most dental manipulations.

3. Administer a tetanus booster if indicated.

ED management of fractured teeth depends on the extent of fracture with regard to the pulp, the extent of development of the apex of the tooth, and the age of the patient.9 Many classification systems are used for describing injured dentition, such as the Ellis system; however, most dentists and maxillofacial surgeons do not use this nomenclature. The most easily understood method of classification is based on a description of the injury.10

**CROWN FRACTURES**

Crown fractures may be divided into complicated and uncomplicated categories. Uncomplicated crown fractures involve the enamel alone or the enamel and dentin in combination.

Uncomplicated crown fractures through the enamel only are not usually sensitive to forced air, temperature, or percussion and generally pose no real threat to the dental pulp. ED treatment is not necessary but may consist of smoothing the sharp edges with an emery board if they are significantly bothersome to the patient. The patient should be reassured that the dentist can restore the tooth with bonding composites and resins. Follow-up is important because pulp necrosis and color change can occur, though rarely (0% to 3% of cases) (Figs. 28.8 and 28.9).11

Uncomplicated fractures that extend through the enamel and dentin are at higher risk for pulp necrosis and need more aggressive treatment (Fig. 28.10; also see Fig. 28.8). The risk for pulp necrosis in these patients is 1% to 7% but increases as time until treatment extends beyond 24 hours.12 Affected patients usually have sensitivity to forced air, percussion, and extremes of temperature. Physical findings are notable for the yellowish tint of the dentin in contrast to the white hue of the enamel. Fractures that are close to the pulp reveal a slight pink coloration. Dentin is porous, which allows oral flora to pass into the pulp chamber and thereby possibly facilitates inflammation and infection. This process occurs predominantly after 24 hours but may do so earlier if the fracture is closer to the pulp. Patients younger than 12 years have a higher pulp-to-dentin ratio than adults do and are therefore at higher risk for pulp contamination. Dentin fracture in a younger patient should be treated more aggressively, and the patient should be seen by a dentist within 24 hours.12

The two primary reasons to treat dental fractures in the ED are (1) to cover the exposed dentin and prevent inflammation and infection and (2) to provide relief of pain. If a tooth is properly covered in the ED, a dentist can later rebuild it with modern composites. A tooth nerve block should be performed before covering the tooth. Dressings that may be considered for covering tooth fractures include calcium hydroxide paste, zinc oxide paste, zinc oxide eugenol, glass ionomer composites, and cyanoacrylates.13-15 Some emergency medicine texts support the use of glass ionomer cements in the ED; however,
Bone wax is sometimes used but is not recommended because it is slightly porous and cannot be used as a base in rebuilding the tooth. Skin adhesives have been used in fracture repair, but they last only a short time inside the mouth and cannot be used as a base in tooth restorations. Their use will probably become more commonplace if their durability improves and clinical studies corroborate their usefulness.

Many patients sustaining deep dentin fractures eventually require a root canal or other definitive endodontic therapy; however, timely application of an appropriate dressing in the ED can prevent contamination and necrosis of the pulp and might prevent the need for a root canal. Even if it does not save the pulp, such a dressing will eliminate the majority of the pain because the dentin is no longer exposed to air. The EP should make sure to remind the patient that anterior tooth trauma may disrupt the neurovascular supply and possibly result in pulp necrosis, change in color, or root resorption.

Complicated fractures of the crown involving the pulp are true dental emergencies (Fig. 28.12; see Fig. 28.8). They lead to pulp necrosis at least 10% to 30% of the time, even with rapid, appropriate dental treatment. Such fractures are distinguished by the pink-red tinge of the pulp. They are usually severely painful, but lack of sensitivity occasionally occurs secondary to disruption of the neurovascular supply of the tooth. Immediate management involves referral to a dentist, endodontist, or oral surgeon. These fractures generally require pulpectomy (complete pulp removal) or, in the case of...
primary teeth, pulpotomy (partial pulp removal) as definitive treatment.\textsuperscript{12,16,17} The longer the pulp is exposed, the greater the chance for abscess development or pulp necrosis. If a dentist cannot see the patient immediately, the EP should relieve the pain with a supraperiosteal injection and cover the pulp with one of the dressings described previously. If bleeding is brisk, it can usually be controlled by having the patient bite onto a gauze pad soaked with epinephrine or phenylephrine. Alternatively, injecting a small amount of lidocaine with epinephrine into the pulp will stop the bleeding and poses no threat to the tooth because the pulp needs to be removed regardless.

If the exposure was prolonged, many authorities and dentists would advocate antibiotic prophylaxis with penicillin or clindamycin, although the effectiveness of this approach has never been proved.\textsuperscript{18} With regard to antibiotic prophylaxis for dental fractures, it is important to remember the following assumptions: it is uncertain when many patients will be able to secure follow-up, and delayed fracture care and poor gingival health raise the risk for pulp necrosis and, potentially, the development of an abscess. Therefore, although it has not been proved that antibiotics are useful in patients with dentin or pulp fractures, such treatment should be considered if the patient has the previously mentioned risk factors or if the consulting dental professional has requested them.

**Luxation and Subluxation**

With subluxation, a tooth is mobile but not displaced, whereas a luxated tooth has been removed, either completely or partially, from its socket. Luxation injuries are further categorized as follows:

- **Extrusive luxation**: The tooth is displaced in a direction toward the crown (Fig. 28.13).
- **Intrusive luxation**: The tooth is forced apically toward the root of the tooth; it may be associated with crushing or fracture of the apex of the tooth (Fig. 28.14).
- **Lateral luxation**: The tooth is displaced facially, mesially, lingually, or distally (Fig. 28.15).
- **Complete luxation**: The tooth is completely avulsed out of its socket (Fig. 28.16).

Teeth that are minimally mobile and minimally displaced do well with conservative management alone. A traumatized tooth will firm up as the alveolar ligament binds to the alveolar bone. The patient should be instructed to eat only a soft diet for 1 to 2 weeks and to follow up with a dentist as soon as possible.

Grossly mobile teeth, however, require some form of stabilization in the ED. Fixation is best accomplished by a dental professional with enamel bonding materials or wire splinting, which are not usually practical in the ED. Many different techniques are available to the EP, although one must...
be aware of the concern for aspiration of teeth or even the splint if the splinting technique fails.

Temporizing splinting techniques available for use by EPs include periodontal paste and self-cure composites. At this time, tissue glues do not have the durability properties required to firmly splint teeth, but this situation may change and tissue glue in combination with splinting wire may eventually be a good option.
of the supporting alveolar bone. Such teeth are frequently immobile and therefore do not require immobilization in the ED, but they often need later treatment by a dentist or an endodontist because of pulp necrosis. Radiographs should be obtained in the ED if it is uncertain whether a tooth is fractured, avulsed, or intruded. The dentist should manage intruded teeth within 24 hours if possible because intruded adult teeth are often associated with alveolar bone fractures. Permanent teeth usually need to be repositioned by the dentist, whereas primary teeth are generally given a trial period to erupt on their own before interventions are undertaken. The EP should always consider the possibility of an intruded tooth if there is a new abnormal space in the dentition because an intruded tooth can cause infection and craniofacial abnormalities if undiagnosed.

Avulsed teeth are true dental emergencies and provide an opportunity for the EP to make a difference in the outcome of the patient. Missing teeth may be intruded, aspirated, fractured, swallowed, or embedded in the oral mucosa. A panoramic radiograph, facial films, or a chest radiograph should be considered to look for fragments of fractured teeth or a missing tooth. Management of avulsed teeth depends on multiple factors, including patient age, periodontal health, and duration of time since avulsion.18 Primary teeth are not replaced because they can fuse to the underlying alveolar bone and cause craniofacial abnormalities or infection and may also interfere with normal eruption of the permanent teeth. Parents should be reassured that prosthetic teeth can be worn until the permanent teeth erupt, if desired, although this is not typically necessary.

Time since avulsion is the most important determinant in the decision whether to reimplant an avulsed tooth. Generally, the longer the tooth is out of its socket, the higher the incidence of periodontal ligament necrosis and subsequent reimplantation failure.19 Periodontal ligament cells usually die within 1 to 2 hours if not placed in an appropriate transport medium.18,20 Many studies have been conducted on the various storage media used to keep the cells of the periodontal ligament viable. Milk, Hank’s balanced salt solution, EMT Toothsaver, Save a Tooth (commercial formulations of Hank’s solution), saliva, water, and Gatorade have all been studied. Cell culture formulations have been developed that cause periodontal ligament cells to not only remain viable but also proliferate; however, they are not practical for ED use. To

**Intrusion and Avulsion**

Intruded teeth have been forced into the alveolar bone and often cause disruption of the attachment apparatus or fracture

---

**Fig. 28.16** Avulsion.

**Fig. 28.17** Periodontal paste.

**Fig. 28.18** Self-cure composite.
date, warmed milk and warmed Hank’s solution (generic or commercial formulation) are best for prehospital and ED use. They each preserve the periodontal ligament for at least 4 to 8 hours, although reimplantation should take place as rapidly as reasonably possible.

The tooth should be placed in some sort of storage medium immediately after avulsion if possible because even 5 to 10 minutes of exposure to air will begin to cause desiccation and death of periodontal ligament cells. Saline is less optimal than the media mentioned earlier but should be used before water or saliva if it is the only option. The tooth should be reimplanted into the socket at the scene by paramedics, but if they are unable to do so, the tooth should be reimplanted as soon as possible in the ED. Preparation of the socket, including suctioning and irrigation, can take place while the tooth is soaking in the storage medium. The patient’s tetanus status should be updated as necessary and the patient discharged home on a soft diet. Many dental professionals recommend antibiotics effective against mouth flora (penicillin or clindamycin) to decrease inflammatory resorption of the root after fractures or avulsions. This, however, has never been proved to be necessary or beneficial. Treatment with antibiotics should be tailored to the individual patient after discussion with the consultant who will see the patient later.

The prognosis of a reimplanted tooth depends on many factors, the most critical being the time until reimplantation. The age of the patient, the stage of development of the root (younger is better), and the overall health of the gingiva are also important. It is always better to keep a native tooth if possible, and that should be the goal of an EP confronted (younger is better), and the overall health of the gingiva are also important. It is always better to keep a native tooth if possible, and that should be the goal of an EP confronted with an avulsed or fractured tooth. A tooth that has been reimplanted often loses the majority of its neurovascular supply and undergoes pulp necrosis, but the periodontal ligament attaches and the tooth will remain a functional unit, thereby obviating an implant or a prosthesis. Complications that can be expected after reimplantation include some resorption of the root and some discoloration of the tooth. These issues can be managed by the follow-up dentist.

Alveolar Bone Fractures
Trauma to the anterior teeth may result in fractures of the alveolar ridge, which is the tooth-bearing portion of the mandible or maxilla. Alveolar ridge fractures often occur in multitooth segments and vary in the number of teeth involved, the amount of mobility present, and the amount of displacement of the affected segment. Dental bite-wing radiographs obtained in the dental office confirm the diagnosis, and facial films or a panoramic radiograph may show a fracture line apical to the roots of the involved teeth.

Treatment consists of rigid splinting of the affected segment, which should be performed urgently by an oral surgeon or dentist. It should ideally be done within 24 hours, but the urgency depends on the extent, mobility, and displacement of the affected segment. The role of the EP is to diagnose the injury, identify any avulsed or fractured teeth, and preserve as much of the alveolar bone and surrounding mucosa as possible. Alveolar bone that is lost, debrided, or missing is difficult for the specialist to repair properly. Patients with alveolar ridge fractures, if nonmobile with good hemostasis, may be discharged with next-day follow-up, but most will require admission or transfer for repair.

**Alveolar Osteitis (Dry Socket)**
Dry socket pain is severe and frequently requires intervention other than oral pain medication. Alveolar osteitis is associated with severe postextraction pain that occurs when alveolar bone becomes exposed and inflamed. It typically occurs when a clot that is present after a tooth extraction becomes dislodged or prematurely dissolves, most commonly 2 to 4 days after a tooth extraction. The cause of disruption of the clot is not completely agreed on but is thought to be secondary to locally increased fibrinolytic activity. The examination is unremarkable with the exception of the missing clot, which is not always obvious to the untrained eye. Smoking, drinking from a straw, periodontal disease, hormone replacement therapy, and being a female are all risk factors predisposing a patient to dry socket. This complication occurs after 2% to 5% of all extractions, although the rate increases if the extraction was especially traumatic or involves an impacted mandibular third molar.

Patients with dry socket usually have little response to nonsteroidal anti-inflammatory drugs or narcotics but experience immediate relief from a dental nerve block. After a dental block, the socket can be irrigated, suctioned, and packed appropriately. The socket may be packed with gauze impregnated with eugenol or a local anesthetic. Gauze tends to dry out and loosen, so it generally needs to be replaced in 24 to 36 hours. The socket may also be packed with a slurry of hemostatic gauze and eugenol (or lidocaine). The hemostatic gauze acts as a matrix to hold the anesthetic in place. Commercial paste for dry sockets (Dry Socket Paste, Alvogyl) can also be applied to the socket. Commercial pastes have the advantage of ease of use, but as with gauze, they will most likely need to be replaced at least once before complete epithelialization of the socket takes place.

Antibiotics can be given to patients with alveolar osteitis, but this is not a common practice, and dry socket heals completely once the socket has been covered. Antibiotics should be prescribed only after consultation with the patient’s dentist or oral surgeon.

**DENTAL INFECTIONS**
Dental infections run the gamut from minor, easily managed infections, to abscesses, to severe, life-threatening deep space infections that require airway management and operative intervention. Dental infections seen in the ED are most commonly secondary to pulp infection or inflammation or to periodontal disease. Disease of the periodontium is usually a chronic condition, but over time, abscesses develop and require emergency treatment.

Diseases of the pulp can be secondary to trauma or operations, but clearly the most common cause is bacterial invasion after carious destruction of the enamel. As enamel is destroyed, carious development progresses rapidly through the dentin and into the pulp chamber and causes an inflammatory reaction known as pulpitis. If the erosion caused by bacteria is large enough to drain the developing inflammation, the patient may remain asymptomatic for a long time. When the drainage becomes blocked, the process progresses to the pulp and periapical space and results in exquisite tenderness. Periapical abscesses follow the path of least resistance, which may be through the alveolar bone and gingiva and into the mouth or into the deep structures of the neck. If the infection has progressed apically through the alveolar bone and
localized swelling and tenderness at the base of the tooth are present, incision plus drainage in the ED is indicated. Antibiotics effective against oral flora should be prescribed.

In the ED differentiation between periapical abscesses and pulpitis is very difficult, and dental bite-wing radiographs are seldom available. Therefore, some physicians begin antibiotic therapy in patients who have not undergone recent dental instrumentation but complain of tooth pain and exhibit tenderness with percussion. Routine administration of antibiotics for tooth pain that is caused by pulpitis, instrumentation, or a localized abscess is not recommended by the dental societies, and a study in the emergency medicine literature suggests that the use of antibiotics for undifferentiated dental pain is not necessary.23,24 Antibiotics have been recommended for odontogenic infections that have spread outside the immediate periapical area or have associated systemic signs, such as fever, swelling, and trismus. Supraperiosteal infiltration (tooth nerve block) should be performed in most cases, not only to provide immediate and long-acting relief but also because it reduces the need for narcotic analgesics even after the anesthetic has worn off.

Periodontal disease, unlike pulpal disease, is usually asymptomatic unless accompanied by an abscess or ulcerations. *Periodontal disease* is infection of the gingiva, periodontal ligament, or alveolar bone, which essentially make up the attachment apparatus of the tooth. *Gingivitis* is inflammation of the gingiva caused by bacteria; in advanced cases, the gingiva may be reddened, painful, and inflamed. In chronic disease, abscess formation occurs as organisms become trapped in the periodontal pocket. The purulent collection generally drains through the gingival sulcus. However, it can become invasive and involve the supporting tissues, alveolar bone, and the periodontal ligament (periodontitis). Periodontal abscesses that are not draining adequately through the gingival sulcus should be drained in the ED. Antibiotics should be prescribed, and saline rinses are encouraged to promote drainage, but chlorhexidine rinses can be substituted for saline in those with more severe disease.

Pericoronitis usually occurs when the wisdom teeth erupt and the gingiva overlying the erupting teeth becomes traumatized and inflamed. The gingiva overlying the crown may entrap bacteria and occasionally become infected, but the patient generally has pain from inflamed gingival tissue. Rarely, however, the localized infection can spread to deeper tissues, such as the pterygomandibular or submaseteric space. Clinically, patients with spread of pericoronal infection are found to have trismus secondary to irritation of the masseter and pterygoid muscles. If the pericoronal infection is localized, saline rinses and oral antibiotics are prescribed with dental follow-up in 24 to 48 hours.

**Deep Space Infections of the Head and Neck**

It is not unusual for odontogenic infections to spread to the various potential spaces in the head and neck. The initial signs and symptoms are varied but usually consist of pain, swelling, difficulty swallowing or speaking, trismus, fever, and chills.

Certain teeth allow infections to spread to particular deep spaces in the head and neck, but rapid spread of these infections can make localizing the exact space difficult. Maxillary extension is likewise possible and can spread to several different spaces and potentially to the cavernous sinus. Cavernous sinus involvement is generally associated with periorbital cellulitis, as well as meningeal signs or a change in mental status.

Deep space infections can rapidly become severe and life-threatening. The submandibular space connects to the sublingual space, and bilateral involvement of the sublingual spaces can result in a condition known as Ludwig angina, an airway-compromising deep space infection that may require airway intervention (Fig. 28.19).

Management of complicated odontogenic head and neck infections focuses primarily on airway management, surgical drainage, and antibiotics. CT has become the imaging modality of choice for deep space infections of the head and neck and should be used to localize and delineate collections of abscess or cellulitis that cannot be precisely determined by physical examination. Airway intervention should be performed early if there is any question of compromise. The EP should administer antibiotics intravenously and obtain surgical consultation early in evaluation and treatment of the patient.

The bacteria usually isolated from deep space infections of the head and neck typically consist of mixed *Staphylococcus* and *Streptococcus* or mixed aerobic and anaerobic flora. Almost half the isolates from odontogenic infections are resistant to β-lactam antibiotics.25 Drugs of choice include penicillin G plus metronidazole or extended-spectrum penicillins such as ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam. These combination antibiotics are effective against β-lactamase–producing bacteria, as well as common oral anaerobes such as *Bacteroides fragilis*. Clindamycin is an effective choice for penicillin-allergic patients, but it should be combined with a cephalosporin such as cefotetan or cefoxitin for resistant organisms. It is prudent to remember that antibiotics are adjunctive therapy only and not a substitute for surgical therapy.

Pharynx and Throat Emergencies

H. Gene Hern, Jr.

**KEY POINTS**

- Viruses cause most cases of pharyngitis, but the modified Centor score represents a scoring system that can increase detection of group A β-hemolytic streptococcal pharyngitis.
- Consider corticosteroids in patients with pharyngitis for symptomatic relief of tonsillar hypertrophy.
- Unilateral pain and swelling may indicate peritonsillar abscess (consider ultrasound).
- Consider epiglottitis in circumstances in which the findings on physical examination do not match the patient’s pain and other symptoms. Visualize the epiglottis to rule out the disease.
- Ludwig angina is characterized by bilateral submandibular swelling, fever, and an elevated or protruding tongue.
- Lemierre syndrome, a suppurative thrombophlebitis located within the internal jugular vein, is a complication of nearby infections in the pharynx or mastoid space.
- Retropharyngeal abscesses in children younger than 6 years are due to infected lymph nodes and in adults are due to local or hematogenous spread. They require imaging to make the diagnosis because examination findings are notoriously unreliable in this population.

**PATHOPHYSIOLOGY**

The structure of the oropharynx also provides multiple types of complications from pharyngeal emergencies. The most obvious potential complication from diseases of the airway is airway compromise. Restrictive spaces such as the hypopharynx and larynx (with the narrow vocal cords and superior epiglottis) provide ample opportunity for even mild inflammation or edema to significantly alter normal airflow through this region. In addition, the proximate location of the great vessels of the carotid artery and internal jugular veins provide fertile ground for infections or complications from airway procedures such as drainage of peritonsillar abscesses. The fascial planes in the oropharynx reach toward vital structures, which when infected may have disastrous results. The deep fascial planes track posteriorly toward the vertebral column, inferiorly into the mediastinum, and superiorly near the cavernous sinus, thus providing opportunities for cervical vertebral osteomyelitis, mediastinitis, or cranial nerve problems.

**ANATOMY**

The pharyngeal anatomy resembles an inverted cone, with the narrowest part at the point where it attaches to the esophagus at the level of the cricoid cartilage and the widest part attaching to the base of the skull. It is a muscular and fibrous tube located immediately behind the nasal cavity and mouth and has many functions. The pharynx connects anteriorly and superiorly with the nasal cavity to allow movement of air into the lungs though a continuously open passage. At its midpoint, the pharynx connects with the oral cavity for passage of nutrition and hydration into the esophagus. Inferiorly, it connect with the esophagus posteriorly and the larynx inferi orly and allows the complex selection of food and air to travel to different organ systems. The pharynx has abundant immunologic tissue to help fight infection—the palatine tonsils, adenoids, and lingual tonsils—which may predispose the host to dangerous circumstances (e.g., airway compromise) if the inflammatory response is too dramatic.

**EPIDEMIOLOGY**

Upper respiratory complaints are the most common reason that patients seek medical care. Pharyngitis is diagnosed in more than 10 million patients per year. Millions of dollars are spent not only on medications and medical visits but also to arrange child care and sick leave for patients unable to go to work or school. Even though most causes of throat pain are benign and self-limited, a number of causes of sore throat may be severe and life-threatening.

The oropharynx plays a vital role in the health of every patient. Not only is it the needed entry point for food and nutrition, but oxygen and carbon dioxide must also move through the oropharynx every minute to maintain metabolic homeostasis. Any disease process that interferes with the function of the oropharynx has the potential to cause significant morbidity and perhaps mortality.

**ACUTE PHARYNGITIS AND TONSILLITIS**

An inflammation of the oropharynx, pharyngitis is predominantly an infectious disease. Pharyngeal pain and dysphagia are some of the more common complaints in outpatient clinics and emergency departments (EDs) alike. Though mostly a benign disease, occasionally the immunologic response to the infection causes severe complications both in immediate
proximity to the tissues of the airway and also systemically. The local inflammation may give rise to straightforward complications such as otitis media, but more dramatic complications such as dehydration, tissue edema, and airway compromise may also occur.

Pharyngeal irritation and inflammation produce throat pain that is worsened by swallowing. Occasionally, this pain may radiate to the ears or feel pressure-like because the eustachian tubes may also be blocked or swollen. The tonsils and pharynx may be erythematous with or without tonsillar enlargement, exudates, petechiae, or lymphadenopathy. Subtle variations or systemic symptoms may be present to aid in the diagnosis, but exact determination of the specific clinical cause of the pharyngitis from clinical criteria alone is notoriously difficult.

**PATHOPHYSIOLOGY**

Viruses cause most cases of pharyngitis. Even the most common cause of bacterial pharyngitis in children, group A β-hemolytic *Streptococcus* (GAβHS), is responsible for only 30% of cases of pharyngitis. In adults, *Streptococcus* species account for 23% of cases, with *Mycoplasma* (9%) and *Chlamydia* (8%) species also being significant.1 Recently, *Fusobacterium necrophorum*, known to be a factor in Lemierre syndrome, has been show to be a causal agent in as many as 10% of cases of pharyngitis in young adults.2

**PRESENTING SIGNS AND SYMPTOMS**

**VIRAL**

In addition to the characteristic pharyngeal pain and dysphagia, viral causes of pharyngitis may also produce low-grade fevers, cough, rhinorrhea, myalgias, or headaches. Viral causes may produce exudates as well, although cervical adenopathy is less common. Common viral causes include rhinoviruses, adenoviruses, Epstein-Barr virus (EBV), herpes simplex virus (HSV), and influenza and parainfluenza viruses. Less common viruses that may cause pharyngitis include respiratory syncytial virus, cytomegalovirus, and primary human immunodeficiency virus (HIV).

Pharyngitis in young adults may be due to infectious mononucleosis, an infection caused by EBV. It is often characterized by thick tonsillar exudates or membranes, as well as other systemic symptoms and signs. Splenomegaly (50%) is frequently present and generalized lymphadenopathy is usually present. Palatal petechiae and periorbital edema may likewise be seen.

Also a disease of young adults, HSV infection may produce a painful and characteristic pharyngitis. HSV pharyngitis is typically accompanied by painful vesicles on an erythematous base. These vesicles occur in the pharynx, lips, gums, or buccal mucosa. Fever, lymphadenopathy, and tonsillar exudates may also be present and last for 1 to 2 weeks. HSV pharyngitis may be either a primary infection or reactivation of a previous infection. In addition, bacterial superinfection of affected tissues may occur.

**BACTERIAL**

The most common cause of bacterial pharyngitis in children is GAβHS. It is less frequently implicated in patients older than 15 years. During epidemics, the incidence may double. Characteristic symptoms include tonsillar exudates, high fevers (temperature > 38.3°C), tender cervical adenopathy, and pharyngeal erythema. Headache, nausea, and abdominal pain may also be found. GAβHS pharyngitis usually lacks the traditional symptoms of viral infections (cough, rhinorrhea, myalgias). It occasionally produces a fine sandpaper-like rash that is termed scarlet fever.

Pharyngitis caused by *Mycoplasma pneumoniae* occurs in crowded conditions, may be associated with epidemics, and typically produces a mild pharyngitis. Symptoms include exudates and a hoarse voice, and it may also be associated with lower respiratory symptoms such as cough and occasionally dyspnea.

*Chlamydia pneumoniae* pharyngitis resembles *Mycoplasma* pharyngitis in its occurrence in epidemic and crowded conditions. This pharyngitis is classically described as severe and persistent with tenderness in the deep cervical lymph nodes and occasional associated sinusitis.

Gonococcal and *Chlamydia trachomatis* pharyngitis have varying manifestations from exudative to nonexudative, mildly symptomatic to severely symptomatic, and transient or persistent. These infections result from orogenital sexual transmission, and asymptomatic carriers exist and may unknowingly spread the disease.

*F. necrophorum*, known to be a factor in Lemierre syndrome, frequently causes pharyngitis in young adults and is a common causative agent of recurrent pharyngitis as well.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**VIRAL**

Diagnostic testing for viral pharyngitis is limited to only a few different specific causes. EBV infection may be diagnosed with a few different tests. The peripheral blood smears of up to 75% of patients with EBV demonstrate atypical mononuclear cells. An EBV monospot test may be positive in up to 95% of adults and 90% of children, but the test may not be positive during the first few days of illness. EBV IgM antibodies develop in 100% of patients but may also initially be negative.

Herpes pharyngitis is diagnosed by serologic tests, herpes culture, or cytopathologic tests from lesion scrapings. Primary HIV pharyngitis may be diagnosed with serologic tests such as Western blot and enzyme-linked immunosorbent assay. New rapid HIV tests using buccal swabs have also been shown to be effective in an ED setting.

**BACTERIAL**

Diagnostic testing for GAβHS is a subject of some controversy. Although the diagnosis of GAβHS infection is important in
preventing many serious complications of streptococcal pharyngitis, including rheumatic fever, accurate diagnosis of GABHS pharyngitis is notoriously difficult. The only valid method of diagnosing acute GABHS infection involves acute and chronic antistreptolysin O titers. However, this method is far from practical in the emergency setting. Throat cultures have a sensitivity of nearly 90% for detecting Streptococcus pyogenes in the pharynx, but their accuracy may vary, depending on recent antibiotic use and culture and collection techniques.

Rapid diagnostic testing for GABHS detects antigens via varying techniques, including latex agglutination, enzyme-linked or optical immunoassay, and DNA luminescent probes. Specificities are reported to be greater than 90% with sensitivities between 60% and 95%. A positive test appears to be a reliable indicator of the presence of GABHS in the pharynx, but a number of factors must be considered. Some patients with a positive test may be asymptomatic carriers, and rapid tests may be negative in patients with low bacterial counts.

In addition to cultures and rapid streptococcal tests, a number of authors have proposed clinical criteria to aid in the diagnosis of GABHS pharyngitis. The most well known are the Centor criteria and the McIssac modifications of these criteria. The modified Centor score gives one point each to temperature higher than 38° C, swollen tender anterior cervical nodes, tonsillar swelling or exudates, absence of upper respiratory tract symptoms (e.g., cough, coryza), and age between 3 and 15 years. If the patient is older than 45 years, a point is subtracted. If the score is 1 or less, no further testing or treatment is warranted. For scores of 2 to 3, further testing may be indicated, such as cultures or rapid streptococcal tests. For scores of 4 or higher, no further testing is required and all patients may receive antibiotics for GABHS pharyngitis (Box 29.1).4,5 In two recent guidelines (from the Infectious Diseases Society of America [IDSA] and the American Society of Internal Medicine [ASIM]), slightly different approaches to patients with pharyngitis have been proposed. In children the guidelines are similar and call for the use of a rapid test in all children; those with a positive test are treated, those with a negative test undergo a throat culture, and those with a positive culture result are treated. The guidelines have suggested different approaches to adults with pharyngitis, however. The IDSA guidelines propose treating all adults in a fashion similar to their pediatric recommendations.3 The ASIM guidelines, though, allow two additional approaches for adults, including performing a rapid test on all adults with a Centor score of 2 or 3 and treating those with a positive test result, as well as empirically treating all patients with a score of 4 or higher. The final approach endorsed by the ASIM suggests testing no adults but treating all adults with a Centor score of 3 or 4 empirically.6 A recent analysis comparing the different recommendations found that an approach using throat cultures had a sensitivity of 100%; approaches using rapid streptococcal tests involving clinical criteria alone had sensitivities of approximately 75%. Furthermore, the specificity of clinical criteria alone was below 50%, thus suggesting that many adults were prescribed antibiotics for pharyngitis unnecessarily.8 Diagnostic testing for other causes of bacterial pharyngitis requires either culture on special media (Thayer-Martin agar for gonococcal infection) or specialized antigen or serologic testing. Mycoplasma infection may be detected by culture, serologic testing, or rapid antigen testing. Antigen detection may also be used for chlamydial infection, as well as culture or serologic testing.

**DIFFERENTIAL DIAGNOSIS**

In addition to the infectious causes of pharyngitis mentioned in this chapter, a number of other infectious and noninfectious causes must be considered in the differential diagnosis of patients with pharyngitis. Among dangerous infections, deep space infections such as retropharyngeal abscesses, peritonsillar abscesses, and epiglottitis must be considered. Noninfectious but potentially serious diseases in the differential diagnosis include drug or allergic reactions, foreign body or caustic ingestion, angioedema, and chemical or thermal burns.

**TREATMENT**

Fortunately, most cases of pharyngitis are acute and self-limited. Supportive care with analgesics and antipyretics and perhaps topical anesthetics (lozenges or sprays) helps in alleviating the symptoms. However, even most infectious causes of pharyngitis rarely cause serious complications.

Among viral causes, few allow specific treatment. HSV infection may be treated with acyclovir, famciclovir, or valacyclovir, all of which produce similar earlier resolution of symptoms but do not eradicate the etiologic agent. Infectious mononucleosis has no effective antiviral agent, but some important aspects of disposition remain important. Patients suspected of having infectious mononucleosis should be advised against contact sports for 6 to 8 weeks because of concern for potential serious splenic injury. Patients with infectious mononucleosis in whom tonsillar edema and hypertrophy severely limit adequate oral hydration secondary to dysphagia may receive corticosteroids (dexamethasone, 6 to 10 mg intramuscularly) to aid in relief of symptoms.

Of all bacterial causes, GABHS is the most common and most often studied. Regardless of the diagnostic strategy used, antimicrobial therapy directed at streptococcal species will

---

**BOX 29.1 Clinical Diagnosis of Streptococcal Pharyngitis**

The modified Centor criteria constitute a scoring system that can increase detection of group A β-hemolytic streptococcal pharyngitis. One point each is assigned to the following features:

- Temperature > 38° C
- Swollen, tender anterior cervical nodes
- Tonsillar swelling or exudates
- Absence of symptoms of upper respiratory tract infection (e.g., cough, coryza)
- Age between 3 and 15 years (if the patient is older than 45 years old, a point is taken off)

If the score is 1 or less—no treatment.

For scores of 2 to 3, further testing may be indicated, such as cultures or rapid streptococcal tests.

For scores of 4 or greater, no further testing is required and all patients may receive antibiotics for group A β-hemolytic streptococcal pharyngitis.
probably be very effective. There are two main reasons to treat GAβHS pharyngitis—to improve symptoms and decrease complications. Patients who receive antibiotics during the first 2 to 3 days of symptoms are likely to improve 1 to 2 days faster than those not taking antibiotics. In terms of complications, the most feared complication of GAβHS infection is acute rheumatic fever. Antibiotic treatment within the first 9 days of infection decreases the rate of rheumatic fever after GAβHS infection. However, the incidence of acute rheumatic fever has fallen drastically in the last few decades such that the number needed to treat to prevent one case of rheumatic fever has risen from 63 to now more than 4000. This is due to the amount of antibiotics prescribed for GAβHS infection over the years, as well as the presence of less virulent strains of bacteria and improved living conditions. Antibiotic use also limits transmission to others and the amount of supplicative complications, including peritonsillar abscesses, retropharyngeal and other deep space infections, otitis, and mastoiditis. Use of antibiotics has no effect on the incidence of poststreptococcal glomerulonephritis.

Penicillin remains an effective choice for GAβHS pharyngitis. Benzathine penicillin, 1.2 million units, or a 10-day course of penicillin VK, 500 mg orally twice per day, both effectively treat pharyngitis and reduce symptoms. The intramuscular route may be more effective in treating streptococcal pharyngitis secondary to compliance issues but is associated with more severe allergic reactions. Alternative regimens include macrolide antibiotics (e.g., erythromycin, azithromycin) and clindamycin. Oral cephalosporins have been shown to result in slightly improved cure rates when compared with penicillins and may be taken over a shorter course (5 days).

Mycoplasma pharyngitis may be treated with a course of macrolide antibiotics or tetracycline or doxycycline. C. pneumoniae pharyngitis is treated for 10 days with doxycycline, trimethoprim-sulfamethoxazole, or a macrolide. C. trachomatis pharyngitis may require repeated courses or prolonged use of antibiotics. F. necrophorum is susceptible to penicillin or clindamycin.

Corticosteroids, in conjunction with antibiotics, decrease the duration of symptoms in patients with pharyngitis without increasing complications. Steroids are particularly useful in patients with profound tonsillar hypertrophy and edema or in patients with severe dysphagia and mild dehydration. By reducing the inflammatory response, steroids allow patients to swallow without significantly reducing the pain sooner.

DISPOSITION

Patients with pharyngitis usually have full resolution of their symptoms without difficulty. However, life-threatening complications do occur. Infectious mononucleosis may lead to airway obstruction, epiglottitis, deep space infections, and distant or systemic disorders such as splenic injury, thrombocytopenia, or hemolytic anemia. Complications of GAβHS pharyngitis include deep space infections, toxic shock syndrome, peritonsillar abscesses and autoimmune-related glomerulonephritis, rheumatic fever, and erythema nodosum. Patients in whom airway compromise is at all a concern should be admitted to the hospital for observation and personnel with advanced airway skills alerted for the potential need for a surgical airway.

PERITONSILLITIS, PERITONSILLAR CELLULITIS, AND ABSCESS

Epidemiology and Pathophysiology

Peritonsillar cellulitis and peritonsillar abscess exemplify the continuum of peritonsillar infections best characterized as peritonsillitis. Peritonsillar infections represent the most common deep infection of the head and neck region. These infections occur more frequently in teenagers and young adults, but they can develop at any age. The infection begins most commonly when tonsillitis spreads beyond the boundary of the tonsillar capsule and invades the potential space between the lateral aspect of the tonsillar capsule and the superior constrictor muscle of the pharynx. The local spread of infection begins as cellulitis but progresses to abscess formation if left untreated. Predisposing factors include chronic tonsillitis, dental infections, smoking, and infectious mononucleosis. Peritonsillitis can occur in patients who have previously undergone complete tonsillectomy.

Presenting Signs and Symptoms

Symptoms of peritonsillitis begin with the symptoms of tonsillitis and progress over a few days to increasing pain and unilateral symptoms. Patients with peritonsillitis often complain of dysphagia, odynophagia, drooling, trismus, and referred otalgia on the affected side. In addition, patients will describe changes in voice (hoarseness or a “hot potato” voice) as a result of decreased movement of the palate. Patients may report recurrent bouts of pharyngitis or trials of antibiotics without resolution of symptoms.

Signs

On physical examination the patient may have trismus, which may prevent clear visualization of the pharynx but may respond to benzodiazepines. Erythematous mucosa and purulent exudates may be present. The distinguishing features of a peritonsillar abscess include unilateral swelling and displacement of the infected tonsil and frequently the soft palate toward the midline with resultant deviation of the uvula to the contralateral side. Peritonsillar abscesses are generally unilateral and can occur in the superior pole of the tonsil.

PATIENT TEACHING TIPS

When to take antibiotics
When to take pain medicine
Return for
- Increased difficulty breathing
- Increased difficulty swallowing
- Worsening pain
- Confusion or changes in thinking
- Worsening fever
DIFFERENTIAL DIAGNOSIS

The differential diagnosis of peritonsillitis includes infectious mononucleosis, cervical adenitis, tubercular granuloma, internal carotid artery aneurysms, and neoplasms. Obviously, infectious causes will be manifested in a more rapid manner than chronic granulomas, masses, or aneurysms. Pulsatile masses or findings that do not suggest an acute infectious cause must be evaluated with other imaging techniques to elucidate the cause of the symptoms.

DIAGNOSTIC TESTING

Plain radiographs do not aid in the diagnosis or treatment of uncomplicated cases of peritonsillitis. Although it is often difficult to distinguish peritonsillar cellulitis from peritonsillar abscess, a number of modalities can aid in diagnosis. For patients who cannot lie down or who are unable to cooperate with needle aspiration, intraoral ultrasound is a useful test. Computed tomography (CT) is helpful in delineating the extent and scope of the abscess, but it may be difficult for the patient to lie supine during the study.

TREATMENT

Pending airway obstruction requires emergency aspiration of a peritonsillar abscess. For less urgent conditions, the classic recommendation was incision and drainage. Needle aspiration, with or without ultrasound guidance, provides a diagnosis, induces less pain, and is easier to perform than traditional incision and drainage. Approximately 10% of needle-aspirated abscesses require repeated aspiration.

Patients should receive antibiotics (penicillin or clindamycin) and steroids for relief of the pain and swelling, regardless of whether the abscess is drained. One strategy if the peritonsillitis is thought to be cellulitis or if the aspiration reveals no purulence is to start antibiotic and steroid treatment and assess the patient in 24 hours to see whether the symptoms are improving or another aspiration is required.

DISPOSITION

Most patients with peritonsillitis can be treated safely and discharged home with antibiotics, steroids, and close follow-up in 24 to 48 hours. For patients with severe dehydration or severe trismus requiring intravenous hydration, a brief inpatient stay may be required. Any patient with tissue edema and potential airway compromise must be admitted to the hospital for observation and potential aggressive airway management.

EPITHELITIS AND SUPRAGLOTTITIS

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Inflammation and edema of the epiglottis may result in rapid and life-threatening airway obstruction if not identified and treated effectively. In addition, the tissues immediately adjacent to the epiglottis (arytenoids, false vocal cords, and pharyngeal wall) may also become edematous and result in a similar infection known as supraglottitis. The signs and symptoms of the two diseases may be remarkably similar, although their populations may be somewhat different. Until introduction of the Haemophilus influenzae type B (Hib) vaccine in the mid-1980s, epiglottitis was a disease of children. The annual incidence decreased dramatically to a very low 0.3 to 0.6 per 100,000 children. Adult epiglottitis appears to be on the rise. One study showed a 31% rise in the incidence of adult epiglottitis over an 18-year period. Incidence rates for adults cluster near 3 per 100,000, with a case fatality rate reported to be as high as 7%. The lower overall bacteremia rates in adults than in children suggest that adults may have more viral causes, as well as other noninfectious causes. Noninfectious causes include trauma, ingestion of caustic substances, or thermal injuries from illicit drug inhalation. Of organisms recovered in blood cultures, Hib still predominates, but Streptococcus and Staphylococcus species may be isolated as well.

PRESENTING SIGNS AND SYMPTOMS

CHILDREN

Epiglottitis in children produces a dramatic progression from a relatively well child to a toxic-appearing one. Eighty-five percent of patients are sick for less than 24 hours. Affected children appear anxious, may be sitting forward in a tripod position, and may have difficult clearing secretions (Table 29.1).

ADULTS

Adults with epiglottitis have a mean age of between 42 and 50 years. Unlike children, adults are usually seen after 2 to 3 days of symptoms. Adults exhibit odynophagia and throat pain rather than the drooling and stridor of pediatric patients. This difference is thought to be due to the larger and more rigid trachea and lack of generous lymph tissue in adults. The pharyngeal pain may be disproportionate to the clinical findings. Fever is frequently absent in adults until the later stages. Additionally, epiglottitis or supraglottitis is frequently misdiagnosed in adults as streptococcal pharyngitis, only to have the true diagnosis made later (Table 29.2).

</table>
complete airway obstruction without warning. Endotracheal intubation must be performed under direct visualization either with a laryngoscope or with a fiberoptic bronchoscope/laryngoscope. At all times, equipment and personnel for emergency cricothyrotomy must be present.

Patients should receive broad-spectrum antibiotics that include coverage against *H. influenzae*, as well as other common bacterial pathogens. Ampicillin-sulbactam and ceftriaxone are both acceptable first-line agents. Steroids and racemic epinephrine have not been conclusively proved to be of benefit in these patients.

**DISPOSITION**

All patients suspected of having epiglottitis or supraglottitis should be admitted to the hospital. Adults without respiratory distress (drooling, stridor, or dyspnea) may be admitted without intubation and observed, but in a carefully monitored setting. The vast majority of children with suspected epiglottitis should be intubated in the operating room and then admitted to the intensive care unit (ICU) for intravenous antibiotics. Rarely, a child with epiglottis may not require intubation. However, this is done only in consultation with the pediatric anesthesiologist and intensivist after they have evaluated the patient. Children with epiglottis who are not intubated should always be admitted to an ICU setting because of their very high potential for rapid deterioration.

**LUDWIG ANGINA**

**EPIDEMIOLOGY AND PATHOPHYSIOLOGY**

First described in 1836, Ludwig angina is a fast-spreading, potentially lethal infection of the submandibular, sublingual, and submental spaces. These spaces effectively function as one unit, and infection can easily spread between them. True Ludwig angina involves all of the submandibular spaces; however, serious and life-threatening infections can occur...
with infection of only some of the spaces. Before the advent of antibiotics and surgical decompression, mortality with this disease approached 50%, but it is now commonly reported to be less than 10%.

Approximately 80% of cases involve patients with odontogenic disease. Patients with infection or recent extraction of the second or third molars are particularly at risk because the roots of these teeth extend below the mylohyoid ridge. Abscesses located in this region can easily perforate the lingual plate of the mandible, thereby allowing direct spread of infection to the submandibular spaces. Other predisposing conditions include deep lacerations or trauma to the floor of the mouth, mandibular fractures, and salivary calculi.

**PRESENTING SIGNS AND SYMPTOMS**

Patients with Ludwig angina appear ill and anxious. Males predominate over females by a ratio of 3:2. The classic symptoms include tooth pain (79%), swelling of the neck or chin (71%), dysphagia (52%), neck pain (33%), respiratory symptoms (dyspnea, tachypnea, stridor) (27%), and dysarthria (18%).

Physical findings in almost all patients include bilateral submandibular swelling, fever, and an elevated or protruding tongue (Figs. 29.2 through 29.4). Trismus is found in approximately half of all patients. Complications of Ludwig angina can be disastrous, with infection spreading to the mediastinum, pericardium, or pleural cavity, as well as the lungs and great vessels.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis in a patient with suspected Ludwig angina should also include Lemierre syndrome (septic thrombophlebitis of the superior internal jugular vein), which is distinguished from Ludwig angina by the unilateral nature of the infection. Tumors in the floor of the mouth can be distinguished from Ludwig angina by their tendency to exhibit much slower growth. Mandibular abscesses are generally unilateral and produce less swelling of the floor of the mouth.

**DIAGNOSTIC TESTING**

Because Ludwig angina is predominantly a clinical diagnosis, diagnostic testing commonly delineates the extent of infection, not whether it is present. Soft tissue lateral neck radiographs may be helpful in showing edema of the soft tissues and air in the soft tissue spaces. If the patient is able to lie supine for a short while, helical CT may be helpful in delineating progression of the abscess and allow more accurate surgical débridement (Fig. 29.5, A and B). If the safety of the patient lying supine is at all in question, the airway must be secured first. At all times the utmost caution is required in these patients, and securing the airway will probably involve the joint capabilities of anesthesia, otorhinolaryngologic, and

**PRIORITY ACTIONS**

Move patients with potential airway compromise to code rooms.

Prepare for an emergency airway procedure:
- Intubation
- Fiberoptic intubation
- Surgical cricothyrotomy

In pediatric patients with possible epiglottitis, laryngoscopy should not be attempted until personnel skilled in emergency airway techniques are present.

Initiate antibiotic therapy early in patients with serious infections.

Perform appropriate imaging of patients for serious infections such as retropharyngeal abscess or supraglottitis when their pain is out of proportion to the findings on examination.
dangerous but fortunately rare complication of nearby infections in the pharynx or mastoid may produce septic emboli. Lemierre syndrome is often caused by the organism *F. necrophorum*, a gram-negative anaerobe that produces endotoxin and is also responsible for many cases of acute and recurring pharyngitis, as well as peritonsillar abscesses.14 *F. necrophorum* can colonize the upper respiratory, gastrointestinal, and genitourinary tracts. Other organisms that may also cause this particular variant of septic thrombophlebitis include *Bacteroides melaninogenicus*, *Eikenella corrodens*, and non–group A streptococci.

**PRESENTING SIGNS AND SYMPTOMS**

The signs and symptoms of Lemierre syndrome may mimic those of other localized infections and include fever, swelling, tenderness, and pain with range of motion of the neck. It does, however, include the additional feature of obstruction of normal blood flow in the affected internal jugular vein, which may cause unilateral swelling, edema, and induration in the tissues on the affected side, regardless of whether they actually infected.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

When considering Lemierre syndrome, one must also consider Ludwig angina or other deep space infections in the neck and parapharyngeal tissues. Whether from odontogenic, lymphatic, or other sources, deep space infections in the neck and pharynx must be taken very seriously.

**DIAGNOSTIC TESTING**

Lemierre syndrome is a diagnosis that when suspected requires confirmatory testing to document involvement of the

---

**Fig. 29.5** A, Computed tomography (CT) scan of Ludwig angina showing infection in the submandibular spaces (arrow). B, CT scan of Ludwig angina showing infection in the submandibular spaces.
internal jugular vein. Soft tissue lateral neck radiographs may be helpful in showing edema of the soft tissues and air in the soft tissue spaces, but they lack the specific information on vein involvement needed to make the diagnosis of Lemierre syndrome. The diagnosis is made most commonly via a contrast-enhanced CT scan of the neck. In addition, magnetic resonance imaging (MRI) may also delineate the extent of involvement of the jugular vein. Both these modalities will also provide information about the surrounding anatomy, including distortion of nearby tissues and localized pockets of infection that must be drained. Other tests that may aid in the diagnosis of Lemierre syndrome include duplex ultrasonography, retrograde venography, and gallium scanning. If there is any question about the safety of the patient lying supine, the airway must be secured first.

TREATMENT

Treatment of Lemierre syndrome must include both heparin and antibiotics. The thrombus provides a nidus of ongoing infection and, subsequently, septic emboli. The anticoagulation effectively limits progression of the thrombosis and, in turn, limits the development of further septic emboli. The initial choice of antibiotics should be broad spectrum. Prolonged high-dose broad-spectrum antimicrobial therapy is recommended because of the high risk for septic emboli and endocarditis. Close consultation with an infectious disease specialist would be helpful in such cases.

DISPOSITION

Patients with Lemierre syndrome clearly need to be admitted to the hospital, and consultation with a vascular surgeon may be helpful if thrombectomy is being considered.

RETROPHARYNGEAL ABSCESS

PATHOPHYSIOLOGY

Even though retropharyngeal abscesses predominantly occur in the pediatric population, adults may also be affected. Pediatric patients possess prominent lymph nodes in the retropharyngeal area, which can become infected and progress to cellulitis and abscess formation. These nodes atrophy by 6 years of age, and the incidence of retropharyngeal abscess drops precipitously.

The cause of retropharyngeal abscesses in the nonpediatric population differs greatly from the local lymph node infections in the age group younger than 6 years. The cause of adult retropharyngeal abscesses ranges from extension of other pharyngeal infections (e.g., parotitis, peritonsillar abscess, tonsillitis, Ludwig angina, dental infections) to instrumentation and other trauma (fishbones or dental instruments) to hematologic spread of systemic infections. Microbiologic testing of retropharyngeal abscesses reveals a diverse array of causative bacteria. Although the preponderance of abscesses are polymicrobial (up to 86%), some species predominate. The majority of aerobic pathogens include Streptococcus and Staphylococcus species, and Bacteroides, Fusiform, and Peptostreptococcus species dominate the anaerobic isolates. Tuberculous and fungal causes must also be considered.

PRESENTING SIGNS AND SYMPTOMS

Patients will have a sore throat, as well as any number of other symptoms, including dysphagia, drooling, odynophagia, neck pain, and a muffled voice. The dysphonia frequently sounds like a duck quack (cri du canard). Patients may complain of a feeling of a lump in their throat and may prefer to lie supine or with their neck extended to keep the swelling in their posterior pharynx from compressing their upper airway. In the pediatric population, many case series have reported the mean age as being 3 years. It is uncommon for children in this age group to describe these symptoms, and the more common complaints are related to feeding, fever, and stridor. On physical examination only a minority of adult patients (37%) will have visible swelling of the posterior pharynx. Other physical findings might include cervical lymphadenopathy, torticollis, and trismus. Palpation of the neck or moving the larynx and trachea side to side (tracheal “rock” sign) may induce pain. Pain and other symptoms out of proportion to the findings on physical examination require further diagnostic testing and evaluation.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Other possible diagnoses to consider in these patients include other pharyngeal infections such as pharyngitis, peritonsillar abscess, and infectious mononucleosis. Abrasions or caustic burns involving the posterior pharynx might produce similar symptoms of dysphagia and odynophagia. Other causes of retropharyngeal swelling and pain may include cervical fracture, hematoma, or other causes of tissue edema such as tendonitis. Finally, distinguishing between a true abscess and pharyngeal cellulitis may be difficult and might be accomplished only with imaging techniques.

DIAGNOSTIC TESTING

Imaging of retropharyngeal abscesses involves two main types of radiologic tests, plain lateral neck radiographs and CT scans. Early studies of normal lateral radiographs suggest that the upper limit of normal for the retropharyngeal spaces is 7 mm at C2 and 22 mm at C6. Anything beyond 7 mm is considered pathologic in both children and adults. In addition, retropharyngeal abscesses will displace the larynx and esophagus anteriorly. If there is still a question about the extent of involvement or the distinction between cellulitis and abscess, CT of the neck (Fig. 29.6) or MRI (Fig. 29.7) will easily elucidate the exact anatomic extension of the abscess. Of course, patients must be stable enough to lie flat in the supine position for the time needed to complete the study. In addition, intraoral ultrasound is another modality with great potential for distinguishing between abscess and cellulitis.
Retropharyngeal infections require broad-spectrum intravenous antibiotics. The antibiotics must cover anaerobes, as well as gram-positive and gram-negative species. Although most retropharyngeal abscesses require surgical drainage, selected cases may occasionally be managed with intravenous antibiotics alone.19 Even if surgical drainage is deferred, admission to a monitored bed after thorough airway evaluation is required.

Complications from retropharyngeal abscesses include spread of infection inferiorly or laterally (Fig. 29.8) into the mediastinum (Fig. 29.9), pericardium, and nearby vascular structures. Osteomyelitis (see Fig. 29.7), transverse myelitis, and epidural abscesses have also been reported.

Temporomandibular Disorders

Laura J. Bontempo

KEY POINTS

- Temporomandibular joint dislocation is usually readily reduced in the emergency department after the patient has been pretreated with analgesic and antispasmodic agents.
- Epistaxis may be the initial complaint of a patient with a more serious systemic illness, such as a clotting disorder.
- When visible blood loss from the nasopharynx has been stopped, the clinician should examine the posterior oropharynx for ongoing occult blood loss.
- Posterior epistaxis accounts for about 10% of nasal hemorrhages and can result in large volumes of blood loss.
- Any abnormal neurologic or ocular physical findings in a patient with rhinosinusitis mandate further investigation to assess for central nervous system extension of the disease.

TEMPOROMANDIBULAR DISORDERS

EPIDEMIOLOGY

The temporomandibular articulations are unique within the body in that they are bilateral joints that are nearly continuously in use. Consequently, the temporomandibular joint (TMJ) is subject to both pain and dislocation. Discomfort of the TMJ was previously referred to as TMJ pain dysfunction syndrome. However, because it was realized that more than just the actual joint can be the source of a patient’s discomfort, the term has evolved to temporomandibular disorder (TMD). TMD is defined as craniofacial pain that involves the TMJ, masticatory muscles, and associated head and neck musculoskeletal structures. It is roughly estimated that more than 10 million people in the United States alone have symptomatic TMD. Most of those affected are women.

TMJ dislocation is an uncommon disorder, with one case series reporting 37 occurrences in 700,000 patient visits.

PATHOPHYSIOLOGY

TMD is probably due to excessive strain on the muscles of mastication with resultant strain on the capsular ligaments of the TMJ. The result is that the mandibular condyle does not articulate properly in its joint. The patient feels pain and senses an occlusal disturbance.

Patients with TMJ dislocation are unable to close their mouth. With normal function, when the mandible is open, the mandibular condyle moves anteriorly and inferiorly. When the mandible closes, the condyle moves posteriorly and superiorly and returns to its original location (Fig. 30.1). TMJ dislocation results when the mandibular condyle moves anterior to the temporal eminence (the anterior portion of the mandibular fossa) (see Fig. 30.1). Once the dislocation occurs, the muscles of mastication spasm, which results in trismus and inability of the patient to return the mandibular condyle to its anatomic position. The dislocation usually results from excessive opening of the mouth, such as occurs with yawning or laughing. TMJ dislocation can also be the result of trauma, seizure, or dystonic drug reactions.

PRESENTING SIGNS AND SYMPTOMS

Unilateral pain in the region of the TMJ and clicking or crepitance that is exacerbated by chewing are the classic complaints of a patient with TMD (Box 30.1). The dull or throbbing pain is localized to the preauricular region or to the muscles of mastication and typically worsens with movement of the mandible, such as when eating or talking. Pain may be most severe in the morning if bruxism is an issue. If a click is present, the patient hears it when jaw opening is initiated. The pain may also radiate to the neck, ears, mandible, or temporal region.

Physical examination should include evaluation of the muscles of mastication by intraoral and external palpation. Palpation may reveal muscular spasm and tenderness. Palpation of the TMJ or muscles of mastication may reproduce the patient’s symptoms and trigger significant pain. The patient may have great pain with any attempt at jaw range of motion. Physical findings are also notable for reduced jaw opening and possible lateral deviation of the jaw.

An inability to close the mouth following extreme jaw opening, such as yawning, is the classic manifestation of TMJ dislocation. If the dislocation is unilateral, the mandible will deviate away from the side of the dislocation (Box 30.2).

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

When considering the diagnosis of TMD, the emergency practitioner must rule out odontogenic causes. If an intraoral cause remains possible after a carefully performed history and physical examination, the patient should be referred to a dentist.
for a full dental evaluation. This evaluation can be done concurrently with the start of TMD treatment. Less common mimics, including jaw tumors and trigeminal neuralgia, should also be considered.

Central nervous system (CNS) disorders must be ruled out in the evaluation of a patient with symptoms suggestive of TMD. The clinician must be especially careful to address this possibility when the patient’s complaints include CNS-related symptoms such as headache and vertigo. A detailed neurologic examination must be performed. Except for possible hyperesthesia immediately around the TMJ, patients with TMD should have no abnormal neurologic findings.

When evaluating a patient for a possible TMJ dislocation, the emergency practitioner must rule out a dystonic medication reaction or a mandibular fracture, both of which can be manifested in similar fashion. In patients with a history of trauma, panoramic radiographic evaluation of the mandible, a TMJ radiographic series, or computed tomography (CT) of the mandible should be performed to assess for a fracture before attempting reduction.

TREATMENT

TEMPOROMANDIBULAR DISORDERS
Management of TMD is primarily directed at improving the patient’s comfort, which is accomplished with analgesia, muscle relaxation, and behavioral modifications. In the absence of trauma, there is no indication for emergency imaging of the TMJ.

Pain should be addressed with antiinflammatory agents (e.g., ibuprofen, 600 mg by mouth every 6 hours, or naproxen, 500 mg by mouth every 12 hours) and narcotic pain medications (e.g., oxycodone, 5 to 10 mg by mouth every 6 hours as needed). Warm compresses should also be applied to the TMJ region for 15 minutes three times per day. Benzodiazepines are used to relieve masseter muscle spasm (e.g., diazepam, 5 mg by mouth every 8 hours as needed). Behavioral modifications include minimizing masseter muscle use through a soft diet and cessation of gum chewing. Reassurance is important because up to 40% of patients will experience resolution of their TMD symptoms with little or no treatment (Box 30.3).²

If bruxism is suspected, dental follow-up should be arranged, and a bite appliance can be considered. To date, experimentation with the use of botulinum toxin to reduce masseter muscle contractility and strength has yielded mixed results.⁷
patient’s pain and masseter spasm facilitates the procedure. Analgesics (e.g., morphine, 5 mg intravenously as needed) and antispasmodics (e.g., diazepam, 5 to 10 mg intravenously titrated to the patient response) should be administered before reduction is attempted. Atraumatic TMJ dislocations do not require imaging.

Once the patient is comfortable, the clinician faces the patient and grasps the mandible inferiorly with the fingers of both hands. The clinician’s thumbs should be heavily wrapped in gauze for protection and then placed on the occlusal surfaces of the mandibular molars. Downward pressure is applied to move the mandibular condyle inferior to the temporal eminence. The mandible is then pushed posteriorly (Fig. 30.2). Once the condyle is posterior to the temporal eminence and pressure is released, the condyle returns to its anatomic position in the mandibular fossa. At the time of reduction, the masseter muscles may contract forcefully and cause the patient to inadvertently clench the jaw. The clinician must be aware of this possibility and ensure that the thumbs are guarded during the procedure and remove the thumbs from the occlusal surface of the molars as quickly as possible. If this method does not work, both thumbs may be placed simultaneously on the dislocated side and the reduction reattempted.

In an effort to minimize risk to the practitioner, an extraoral approach to TMJ reduction was proposed by Chen et al. in 2007. The physician faces the patient and places a thumb on the palpable coronoid process that is displaced anteriorly. The fingers of that hand are placed on the mastoid process for stability. On the nondislocated side, the thumb is placed on the zygoma and the fingers hold the mandible angle. The nondisplaced side of the mandible is pulled anteriorly while concomitant pressure is applied posteriorly to the displaced coronoid process. Although this approach is less successful than the traditional approach, there is no risk of injury to the practitioner.

When reduction of the TMJ has been accomplished, the patient needs to avoid excessive mouth opening to prevent recurrent dislocation and may be discharged home. Postreduction pain can be treated with analgesics and antispasmodics. Advising a soft diet for 2 weeks will also minimize the patient’s discomfort. The patient should be evaluated by an oromaxillofacial surgeon within 2 weeks.

**EPISTAXIS**

**Epidemiology**

The incidence of epistaxis is unknown, but it is estimated to occur in up to 60% of all individuals. The vast majority of these episodes are self-limited and only 6% require medical attention. Epistaxis affects both adults and children, with a higher incidence in children younger than 10 years and adults older than 35 years.

The anterior nasal septum is the source of bleeding in 90% of patients with epistaxis; the posterior nasal septum and lateral nasal wall account for 10% of cases of nasal bleeding. Posterior nasal hemorrhage is more common in the elderly population.

**Pathophysiology**

The nasal mucosa is a highly vascular area, and any disruption of the mucosa can result in bleeding. Although epistaxis can be caused by trauma, this is not the most common cause. Bleeding more commonly results from upper respiratory infections (URIs), a dry environment, nasal foreign bodies, allergic rhinitis, nasal mucormycosis, topical nasal medications (including antihistamines and corticosteroids), and drugs taken intranasally such as cocaine (Box 30.4). Additionally, epistaxis may be the initial symptom of a primary or secondary systemic bleeding disorder. One study found that 45% of patients with bleeding severe enough to warrant hospitalization had an associated systemic disorder that may have contributed to the epistaxis.

The relationship of hypertension to epistaxis is controversial. It is unclear whether elevated blood pressure is the cause or the effect of epistaxis; therefore, hypertension alone is not known to be an independent risk factor for nasal hemorrhage.

The Kiesselbach plexus is located at the anterior portion of the nasal septum and is the source of bleeding in patients with anterior epistaxis. The plexus is supplied by branches of the
internal and external carotid arteries via the sphenopalatine, ethmoidal, and superior labial arteries. Another name for the Kiesselbach plexus is the Little area. The posterior nasal septum and lateral nasal wall are supplied by the sphenopalatine artery, which is the source of bleeding for posterior epistaxis.

Functionally, epistaxis is considered anterior when the site of bleeding can be visualized in the anterior portion of the nasopharynx. Posterior nasal hemorrhage cannot be directly visualized and occurs in the posterior or lateral parts of the nose.

**PRESENTING SIGNS AND SYMPTOMS**

Epistaxis may be manifested as minor bleeding with small quantities of blood dripping from the nares or as major bleeding with the patient vomiting blood. Approximately 90% of cases of epistaxis are anterior and the bleeding source is unilateral. Many patients, however, have blood flowing from both nares because blood from the unilateral bleeding source travels around the septum posteriorly and exits on the other side.

Patients with epistaxis may arrive at the ED with various home treatments in progress. All foreign bodies (cotton, tissues, tampons) should be removed from the nose after the patient arrives to better assess the location and quantity of bleeding.

Important historical elements include the duration of the bleeding, laterality, estimated blood loss, recent trauma, and other associated symptoms.

Obtaining a detailed history is often the key to determining the cause of the patient's epistaxis. The clinician must know whether the patient has recurrent epistaxis, easy bruising, or other sources of bleeding, such as when shaving or brushing the teeth, or is taking a platelet inhibitor or anticoagulant medication. The past medical history is important in a patient who has hepatic disease, atherosclerosis, Osler-Weber-Rendu disease (hemorrhagic telangiectasia), diabetes mellitus, or cancer with ongoing chemotherapy treatment because each of these conditions is a risk factor for epistaxis. Women are more prone to epistaxis during pregnancy.

Trauma, nose picking, recent otorhinolaryngologic surgery, nasal foreign body, URI, nasal polyps, and exposure to a low-humidity environment all predispose to epistaxis and should be addressed in the patient's history. The family medical history may reveal recurrent epistaxis in multiple family members. In the absence of a hereditary bleeding disorder, such a history suggests familial idiopathic epistaxis. A social history must also be obtained to identify alcoholism, intranasal drug use, or domestic violence.

Physical examination of a patient with epistaxis must focus on the nasopharynx and oropharynx; however, a complete examination is helpful. A skin examination may reveal ecchymoses or petechiae (suggestive of a systemic bleeding disorder), spider angiomas or caput medusa (suggestive of hepatic disease), or signs of trauma. Cardiac examination may demonstrate an irregular heartbeat and should prompt the clinician to inquire further about anticoagulant medications.

Concurrent with examining the nasal mucosa, the posterior oropharynx must also be evaluated. The nares may be occluded with nasal packing or clotted blood but continue to have significant blood loss into the oropharynx. The patient swallows this blood, and without a careful examination, the ongoing loss may not be evident until hematemesis or hemodynamic instability develops.

Alternatively, a patient may have a chief complaint of hemoptysis. If a patient has low-volume nasal bleeding with blood flowing posteriorly into the oropharynx, coughing up gross blood may be the initial symptom of epistaxis.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Mechanical causes of epistaxis, such as trauma, nose picking, nasal foreign bodies, and nasogastric or nasotracheal intubation, directly disrupt the nasal mucosa. Blood dyscrasias, hepatic disease, platelet inhibitors, and anticoagulant medications result in decreased blood clotting and predispose the host to bleeding. Infectious causes include sinusitis, rhinitis, mucormycosis, and URIs that result in nasal congestion and vasodilation. In women, both endometriosis and pregnancy must be considered as causes of epistaxis. Environmental factors also play a role in the incidence of epistaxis. Visits to the ED for the treatment of epistaxis are more common in the winter months. This has been proposed to be due to lower ambient humidity and subsequent drying of the nasal membranes during the winter season. Barotrauma can also incite epistaxis.

Recurrent, refractory unilateral epistaxis merits investigation for a possible neoplastic etiology, especially with abnormal findings on neurologic examination.

In patients with larger-volume hemorrhage, hematemesis may be the initial complaint. Once the emesis has been controlled, examination of the oropharynx shows blood entering superiorly from the nasal cavity. The clinician can then work to localize the source of bleeding in the nose without being misled into investigating a gastrointestinal source.

**TREATMENT**

In the prehospital setting or if the patient has to wait before being seen in the ED, the patient can apply direct pressure to the area by squeezing the soft tissue portion of the nose with the fingers. The nares are successfully compressed when a change in the patient's voice is heard.

Standard supplies for the treatment of epistaxis include suction with a Frazier tip, nasal speculum, bayonet forceps, cotton-tipped applicators, silver nitrate cautery sticks, packing

nasal cavity is necessary. This can be accomplished with non-adherent ribbon gauze packing or a nasal tampon or balloon. Preformed nasal tampons and nasal balloons are now widely available and are easily inserted. The tampon or balloon is lubricated with a water-based lubricant and then directed posteriorly into the nasal cavity. The tampon should be placed gently but firmly and quickly into the nasal cavity. If it is inserted too slowly, the first part may expand from contact with blood before insertion is complete, which makes further insertion more difficult for both the patient and clinician. If after insertion the tampon is not fully expanded, saline or a vasoconstrictive agent (see Box 30.5) can be dripped into the nasal cavity until expansion is achieved. If a balloon is used, it will need to be inflated with saline or air, depending on the model used. If nonadherent ribbon gauze is to be used instead, the technique is to insert the packing in an accordion pattern from posterior to anterior and inferior to superior. If the septum bows to the contralateral side after packing, packing the other side may be necessary. Pain medication may be needed to alleviate the discomfort from nasal packing. The packing should remain in place for 1 to 3 days.

Bleeding from posterior epistaxis is more challenging to control. By definition, the bleeding site is not readily visualized, thus making compression and treatment more difficult. The most rapid method for controlling posterior epistaxis is insertion of a posterior balloon device. Typically, this device has a double-balloon design, one balloon to tamponade the posterior nasal cavity and the other for the anterior nasal cavity. After the device is lubricated, it is inserted into the nasal cavity to its hub. The posterior balloon is inflated and the hub is then drawn out away from the nose until resistance is met. Resistance indicates that the posterior balloon has set in the posterior nasal cavity and is not in the pharynx. Next, the anterior balloon is inflated. The quantity of saline required to fill each balloon varies by device but is typically 7 to 10 mL for the posterior balloon and 15 to 30 mL for the anterior balloon.¹⁶

If a posterior balloon device is not available, a Foley catheter can be used in its place. A 12- to 14-French catheter with a 30-mL balloon is used. The catheter is inserted through the nose until the noninflated balloon can be seen in the posterior oropharynx. The balloon is then inflated with 10 mL of saline, and the catheter is slowly withdrawn from the nose until resistance is met. While traction is maintained, the anterior nasal cavity is packed with ribbon gauze. The catheter is secured by placement of a padded umbilical clamp or other equivalent device around the catheter at the point where it exits the nostril. Securing the catheter properly is extremely important. If the catheter is allowed to migrate posteriorly, the inflated balloon descends into the oropharynx and possibly the trachea and obstructs the airway. Using a Foley catheter for control of posterior epistaxis is only a temporary technique, and the catheter should be exchanged for a safer double-balloon device as soon as possible.

For patients with massive epistaxis, use of nasal tampons and balloons is the fastest way to minimize or stop the bleeding. Bilateral anterior tampons or balloons are placed and then the oropharynx examined. If active bleeding continues into the oropharynx, one tampon or balloon is removed and replaced with a posterior balloon device. If significant bleeding continues, the second tampon or balloon is removed and a second posterior balloon inserted. Immediate

**RED FLAGS**

Epistaxis
- Epistaxis may be the initial manifestation of a primary or secondary blood dyscrasia.
- Occluded nares may mask ongoing bleeding.
- Hematemesis may be the initial complaint in patients with large-volume bleeding.
- An antihypertensive agent (i.e., beta-blocker) can mask the early stages of hemorrhagic shock by limiting tachycardia.

---

After removal of the pledgets, the nasal cavity and oropharynx are inspected. If the source of bleeding is identified in the nose and the oropharynx is dry, anterior epistaxis has been confirmed. For anterior epistaxis in which vasoconstriction has mostly controlled the bleeding, chemical cautery with silver nitrate can occur. For this reason, the cautery stick should not be in contact with the nasal mucosa for more than 15 seconds, and bilateral septal coagulation should be avoided. Bilateral coagulation can lead to septal ischemia, necrosis, and perforation.

Another approach to anterior epistaxis is to apply a topical hemostatic packing agent, such as gelatin foam or oxidized cellulose, directly to the bleeding area. These products will be absorbed or degrade and do not require removal.

If neither of the preceding measures is successful, direct compression of the mucosa through packing the anterior
otolaryngologic consultation is then necessary. Bilateral posterior balloons should be in place for the minimal amount of time possible. Fluid resuscitation is then begun for any patient with significant blood loss or signs of shock.

Laboratory tests have a limited role in patients with epistaxis. Patients with low- or moderate-volume anterior bleeding who have no known blood dyscrasia and who are not taking anticoagulant medications do not require any laboratory studies.\textsuperscript{12}

If, however, the patient’s history or physical examination raises concern for a systemic cause of the epistaxis, studies should be ordered as appropriate for the clinician’s specific suspicions. Such studies may include a prothrombin time, activated partial thromboplastin time, coagulation factor levels, bleeding time, vitamin K level, and liver function tests.\textsuperscript{16} In patients exhibiting signs of shock, the hematocrit should be checked to obtain a starting value with which to compare serial measurements. Additionally, blood typing and screening may be necessary for a possible transfusion.

Otolaryngologic consultation is not routinely necessary and should be reserved for refractory epistaxis, for which endoscopy for direct visualization and cauterization, surgical vessel ligation, or embolization may be necessary.\textsuperscript{11}

**FOLLOW-UP AND NEXT STEPS IN CARE**

A hemodynamically stable patient with anterior epistaxis in whom hemostasis has been achieved and maintained should be discharged home. The patient is instructed to avoid nose blowing, bending over, straining, closed-mouth sneezing, and any activity that raises the risk for nasal trauma. In dry environments, humidifiers and saline nasal spray are recommended to help keep the nasal mucosa moist. Pain medications are prescribed as needed for patient comfort; however, aspirin products should be avoided. Any patient with anterior packing or recurrent epistaxis must be evaluated by an otorhinolaryngologist in 24 to 72 hours.

Patients with nasal packing or balloons should be treated with antistaphylococcal antibiotics to minimize the risk for sinusitis and toxic shock syndrome.\textsuperscript{17} Drug choices include amoxicillin–clavulanate potassium, 875 mg two times per day, and cephalexin, 500 mg four times per day. The packing should be left in place for 1 to 3 days and antibiotics continued until the packing is removed. Nasal packing containing antibiotics is also available; these products have been shown to inhibit the growth of nasal flora and may supplant the need for additional systemic antibiotics.

Patients with posterior epistaxis require admission to the hospital. If a posterior balloon were to become dislodged and migrate posteriorly, airway compromise could occur. Additionally, such a patient may have a drop in PaO\textsubscript{2} and a rise in PaCO\textsubscript{2}; after placement of posterior packing. Bradycardia and other cardiac dysrhythmias have also been reported. The mechanism of these events is unclear.

**PATIENT TEACHING TIPS**

**Epistaxis**

Avoid nose blowing, bending over, and straining.

Be sure to open your mouth when you sneeze.

Avoid any activity that puts you at risk for nasal injury.

Use humidifiers and saline nasal spray to help keep the interior of your nose moist.

Take pain medications as needed.

Do not take aspirin or aspirin products.

Follow up with an otorhinolaryngologist in 24 to 72 hours.

Take your antibiotics as prescribed. It is important that you continue to take antibiotics as long as your nasal packing or balloon is in place.

Do not put anything into your nose.

If bleeding recurs, compress your nose by squeezing the bottom half of it with your thumb and index finger. Hold this compression for 10 minutes. If bleeding continues beyond this time, see your doctor or return to the emergency department.

See your doctor or return to the emergency department if a fever or rash develops.

**PRIORITY ACTIONS**

**Epistaxis**

Apply a topical vasoconstrictive agent to the nasal mucosa.

Examine the nasopharynx and the posterior oropharynx to localize the source of bleeding.

Chemical cautery should be used with caution and bilateral septal cautery should be avoided to minimize the risk for septal injury.

Ensure that a posterior nasal balloon is properly secured to avoid airway occlusion.

**SINUSITIS**

**EPIDEMIOLOGY**

Sinusitis is an inflammatory disease of the paranasal sinuses, and rhinitis is an inflammatory disease of the membranes lining the nose. Because sinusitis without associated rhinitis is rare, the term *rhinosinusitis* is now the accepted nomenclature for this disease complex.\textsuperscript{18-22} In much of the current literature, however, the terms *sinusitis* and *rhinosinusitis* are used interchangeably.

Rhinosinusitis is estimated to affect one in seven adults in the United States and has a significant impact on missed workdays and health care costs.\textsuperscript{23,24} It is a complication of URI in 5% to 10% of children and 0.5% to 2% of adults. The actual number of people affected by rhinosinusitis may be significantly higher than reported because of the multitude of over-the-counter sinus medications available.

Over the past decade, five major expert organizations have generated guidelines on the definitions and treatments of rhinosinusitis and its subtypes.\textsuperscript{16-22} There is variation among many of the guidelines’ definitions and recommendations. The information presented in this chapter reflects the areas of greatest consensus among the expert groups.

*Rhinosinusitis* is the parent term for several subtypes of disease. In acute rhinosinusitis (ARS), symptoms last 4 weeks or less; recurrent ARS is defined as three or more episodes of ARS within 1 year, with resolution of symptoms between
episodes; and chronic rhinosinusitis requires symptoms for 12 weeks or longer.  

### PATHOPHYSIOLOGY

There are four pairs of paranasal sinuses: frontal, maxillary, sphenoid, and ethmoid. Maxillary sinusitis is the most common, followed by ethmoid, frontal, and then sphenoid sinusitis.

Each sinus drains through an ostium, which communicates with the nose. The frontal, maxillary, and anterior ethmoid sinuses empty into the medial meatus, between the middle and inferior turbinates. This region is termed the ostiomeatal complex. Obstruction of this complex is a critical step in the development of rhinosinusitis.

Each sinus is lined with ciliated epithelium and mucous goblet cells. Healthy sinuses have relatively few mucus-producing goblet cells, and the cilia beat the mucus toward the ostium of the sinus. The patent ostium allows the free flow of mucus and air from the sinus to the nose. When an ostium is occluded, air and mucus no longer flow freely, new mucus-producing cells develop, and mucostasis results.

### PRESENTING SIGNS AND SYMPTOMS

The diagnosis of ARS is based on three signs or symptoms: nasal congestion, obstruction, or blockage; anterior or posterior purulent rhinorrhea; and facial pain or pressure. Other suggestive symptoms support the diagnosis but serve only as adjuncts.

A detailed history to determine the duration, severity, and course of the symptoms is the only readily available tool to differentiate acute viral rhinosinusitis from acute bacterial rhinosinusitis (see Fig. 30.2). It can be challenging to differentiate early rhinosinusitis from URI because viral URIs are the most common event precipitating rhinosinusitis and the two may be present concurrently.

The signs and symptoms of chronic rhinosinusitis include those of ARS plus a decreased sense of smell. The symptoms are often more vague and less severe and, by definition, must be present for 12 weeks or longer.

Physical examination will reveal nasal mucosal erythema and edema leading to nasal obstruction. Purulent secretions may also be seen in the nose or the posterior oropharynx. Purulent secretions have the highest positive predictive value for rhinosinusitis of any physical finding. The nasal cavities must also be thoroughly inspected for foreign bodies, especially in children.

Sinus tenderness to percussion may be present on examination, although this finding is neither sensitive nor specific. Transillumination of the frontal and maxillary sinuses is also neither sensitive nor specific, and it is not possible to differentiate a fluid-filled sinus from a congenitally small sinus after a single evaluation. The clinician must examine the oral cavity for evidence of a dental infection, which can be the source of maxillary sinusitis. Periorbital edema may also be found.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The diagnosis of ARS is clinical, and in the absence of specific concerns raised by the history and physical examination, no imaging or laboratory tests are warranted. Nasal cultures may be considered during outpatient care in the event of treatment failure. Evaluation for systemic disorders predisposing to rhinosinusitis, such as cystic fibrosis or immunodeficiency, can be done on a nonemergency basis.

The infectious organisms causing rhinosinusitis are most commonly viral, then bacterial, then fungal. The most common viruses are rhinovirus, parainfluenza virus, and influenza virus. The most common bacterial pathogens of ARS and recurrent ARS in an immunocompetent host are Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis. Rhinosinusitis pathogens more commonly found in immunocompromised hosts are Pseudomonas aeruginosa, Rhizopus, Aspergillus, Candida, Histoplasma, Blastomyces, Coccidioides, and Cryptococcus. P. aeruginosa is also a common pathogen in patients with cystic fibrosis.

The pathogens of chronic rhinosinusitis include those of acute bacterial rhinosinusitis plus group A streptococci, Staphylococcus aureus, P. aeruginosa, and fungi.

Noninfectious causes include congenital diseases that inhibit ciliary function, such as cystic fibrosis and Kartagener syndrome; autoimmune diseases, such as Wegener granulomatosis and sarcoidosis; anatomic obstruction, such as from nasal polyps, nasal tumors, or foreign bodies; and facial trauma that directly disrupts sinus drainage.

Any abnormality found on neurologic or ocular examination in a patient with rhinosinusitis must raise concern for CNS extension of the disease and warrants imaging. CT or magnetic resonance imaging should include the brain, orbits, or sinus (or any combination of these structures), depending on clinical suspicion.

Acute or chronic frontal rhinosinusitis can lead to erosion through the frontal bone and a resultant subperiosteal abscess.
known as Pott puffy tumor. In addition to signs and symptoms of rhinosinusitis, patients with this disorder have a severe localized headache, swelling of the forehead, and possibly orbital abnormalities. These infections are most commonly polymicrobial. Frontal sinusitis can also lead to osteomyelitis. Complications of fronto sinusitis are most common during the second and third decades of life.

Intracranial complications of rhinosinusitis, such as an intracranial abscess, meningitis, epidural abscess, subdural empyema, and cavernous sinus thrombosis, are serious sequelae of the disease. Disease can progress intracranially through direct extension or via thrombophlebitis of the diploic veins. Any focal neurologic deficits found on examination must raise concern for intracranial extension of rhinosinusitis. Patients with subdural empyema exhibit systemic toxicity, nuchal rigidity, and photophobia, as well as cranial nerve deficits. The emergency practitioner must maintain a high index of suspicion. A review of patients found that headache and fever without other neurologic abnormalities were the most common manifestations of early intracranial complications of rhinosinusitis.

Pansinusitis leads to orbital sequelae in 60% to 80% of patients. Preseptal cellulitis is the most common complication. Clinical findings suggestive of preseptal cellulitis are periorbital edema without any associated change in vision or limitation of ocular mobility. Orbital cellulitis, orbital subperiosteal abscesses, and orbital abscesses are other complications of pansinusitis; they are manifested as periorbital edema, proptosis, orbital pain, and limitations in ocular mobility.

**TREATMENT**

Treatment of ARS is primarily based on reducing the obstruction of the ostiomeatal complex and thereby relieving the patient’s discomfort.

Intranasal corticosteroids are known to decrease nasal inflammation and may therefore improve ostial patency. These agents have very few identified side effects and are effective in reducing symptoms even as monotherapy. Mometasone nasal spray, 200 mcg in each nostril twice daily, may be used.

Topical and oral α-adrenergic decongestants are often prescribed for patients with rhinosinusitis to induce vasoconstriction and reduce nasal mucosal swelling, thereby improving ostial patency and sinus drainage. No controlled clinical trials, however, have examined the efficacy of these agents, and the recommendations by the five expert panels are widely disparate. There is no evidence that decongestants are harmful in patients with rhinosinusitis, and therefore the decision regarding their use is left to the clinician. Topical sprays, such as oxymetazoline, two sprays in each nostril every 12 hours, or oral decongestants, such as pseudoephedrine, 60 mg every 6 hours, should be considered on the basis of the risk-to-benefit profile of the individual patient. Decongestant nasal sprays should not be used for longer than 5 days because of the risk for rebound nasal congestion (rhinitis medicamentosa).

Antihistamines are a useful adjunct for patients whose rhinosinusitis has an allergic cause. Diphenhydramine, 25 to 50 mg every 6 hours, loratadine, 10 mg daily, or fexofena-

dine, 180 mg daily, may all be used. No studies have indicated that antihistamines play a role in nonallergic rhinosinusitis.

Saline nose drops prevent crusting of nasal secretions and facilitate elimination of these secretions. Physiologic saline and hypertonic saline sprays both increase mucociliary clearance and increase nasal airway patency. Saline nose drops, normal or hypertonic, may be a useful adjunct to aid in relieving the symptoms of rhinosinusitis.

Guaifenesin is an expectorant that decreases sputum viscosity. It has been shown to improve the ease of sputum expectoration in patients with respiratory infections but has not been demonstrated to aid in the management of rhinosinusitis (Box 30.7).

The vast majority of cases of ARS are caused by viruses, with only 0.5% to 2.0% estimated to have a bacterial cause. For this reason, antibiotic treatment should be initiated only in patients for whom the clinician has high suspicion of acute bacterial rhinosinusitis (Table 30.2).

First-line antibiotic therapy is amoxicillin. If the incidence of β-lactamase–positive *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis* infection is high in the area of patient care, adults should be treated with amoxicillin–clavulanate potassium. Alternatively, first-line agents are certain second- and third-generation cephalosporins. Third- or fourth-generation quinolone antibiotics are also appropriate agents for adult acute bacterial rhinosinusitis. Azithromycin or clarithromycin are additional treatment choices, but the local resistance patterns of *S. pneumoniae* and *H. influenzae* must first be assessed. The clinician should tailor the choice of antibiotic to the specific resistance patterns of the practice environment. See Box 30.8 for doses and duration of treatment.

**BOX 30.7 Treatment of Acute Rhinosinusitis**

- Intranasal corticosteroids
- Decongestants
- Antihistamines if an allergic cause is suspected
- Saline nasal spray
- Antibiotics only if the signs and symptoms are consistent with acute bacterial rhinosinusitis

266
Previously, sulfamethoxazole-trimethoprim was a popular antimicrobial agent for the treatment of rhinosinusitis; however, as resistance to it has increased, its clinical utility has become limited.20 Acute bacterial rhinosinusitis should be treated with antibiotics for 10 to 14 days (except azithromycin, as noted previously). The patient should be reassessed 3 to 5 days after antibiotic treatment has begun. If no improvement is seen, concern for resistant organisms is raised, and a change in antibiotics should be considered. Chronic rhinosinusitis is treated with a 21-day course of antibiotics, although data supporting the optimum duration of treatment are minimal.22,23

ARS for is treated for 10 days, unless otherwise noted. Chronic rhinosinusitis is treated for a minimum of 21 days.

Any patient with evidence of ocular or intracranial extension of sinus disease requires immediate otolaryngologic, ophthalmologic, or neurosurgical consultation (or any combination of the three). Broad-spectrum intravenous antibiotic therapy, such as with a third-generation cephalosporin and vancomycin, must be started.34 However, because many of these complications require surgical intervention, the choice of antibiotic should be made in conjunction with the surgical service. A patient with this complication must be admitted to the hospital.

Esophageal Disorders

Todd A. Guth

SECTION IV GASTROINTESTINAL DISEASES

Esophageal Disorders

Todd A. Guth

KEY POINTS

- Esophagitis is inflammation or infection of the esophagus and can be caused by reflux of gastric contents, infectious organisms, corrosive agents, or direct contact with swallowed pills.
- *Candida* species, cytomegalovirus, and herpes simplex virus are the most common organisms that infect the esophagus of an immunosuppressed patient.
- The most dangerous esophageal foreign body is a disc (button) battery, which can cause a chemically induced perforation in as little as 4 hours.
- Esophageal perforation may initially be manifested as nonspecific chest symptoms. The condition can rapidly progress to mediastinitis, overwhelming sepsis, and death.
- Esophageal motility disorders represent a heterogeneous group of conditions that result from derangement in peristalsis of the esophagus and abnormal functioning of the lower esophageal sphincter.

REFLUX ESOPHAGITIS

EPIDEMIOLOGY

Gastroesophageal reflux disease (GERD) describes a constellation of symptoms or complications that result from reflux of gastric contents into the esophagus. Even though approximately 40% of adults in the United States suffer from symptoms of heartburn at least once per month, the overall prevalence of GERD is just 14%. GERD represents a spectrum of disease from nonerosive to erosive esophagitis and finally Barrett esophagus. Common complications of GERD include esophageal strictures and the development of esophageal adenocarcinoma. Within the United States, the incidence of esophageal adenocarcinoma is increasing at an alarming rate of 4% to 10% per year.

PATHOPHYSIOLOGY

A number of conditions and lifestyle choices increase the risk for reflux esophagitis (Box 31.1). The primary pathophysiologic mechanism contributing to the development of GERD is an incompetent lower esophageal sphincter (LES). Inability of the LES to prevent reflux of stomach contents is influenced by esophageal anatomy, impaired gastrointestinal motility, acid hypersecretion, and increased abdominal pressure. Patients with a higher incidence of hiatal hernias, low LES pressure confirmed by manometry, and increased levels of reflux confirmed by esophageal pH monitoring have been shown to experience more severe GERD symptoms.

The entire esophageal lumen is lined with stratified squamous epithelium, which is susceptible to injury by acidic gastric contents. Gastric acid, bile, or pepsin that passively regurgitates into the esophagus can irritate the mucosa and may cause erosions and ulcerations. In cases of persistent reflux, a metastatic columnar lining may replace the normal stratified squamous epithelium; this premalignant condition is called Barrett esophagus. Studies have demonstrated a clear relationship between Barrett esophagus and the development of esophageal adenocarcinoma.

PRESENTING SIGNS AND SYMPTOMS

The most common symptom of reflux esophagitis is “heartburn,” or the epigastric, retrosternal burning sensation that typifies GERD. Heartburn often radiates to the back and neck and may be described as burning, pressure, squeezing, or sharp pain. With severe GERD, patients may demonstrate diaphoresis, dyspnea, nausea, and vomiting. The entire symptom complex may be clinically indistinguishable from cardiac ischemia.

Heartburn is more severe when patients are supine, bend forward, wear tight clothing, or consume large meals. The pain may last from minutes to hours and may resolve spontaneously or with antacids. Patients with nocturnal symptoms often complain of “water brash,” which is the bitter, metallic taste of regurgitated gastric contents noted on arising from sleep. Approximately 80% of patients with GERD have primarily nocturnal symptoms that are exacerbated by being supine. Patients with daytime symptoms have postprandial heartburn and fullness even when upright. GERD can cause chronic cough, recurrent throat clearing, and wheezing as a result of aspiration of gastric contents from the esophagus into the trachea and larynx. A complaint of dysphagia in the setting of GERD is an ominous sign that should prompt endoscopic evaluation for underlying strictures or adenocarcinoma.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

GERD is a clinical diagnosis elicited by a detailed and directed history of the present illness. GERD should be diagnosed only after other life-threatening causes of chest pain have been convincingly excluded (Box 31.2). Providers must consider...
the potential life threats and serious medical conditions that can be manifested in a similar fashion to GERD. A thorough history is the most important consideration in the differentiation diagnosis of patients with GERD-like symptoms. The initial history should be obtained in concert with immediate electrocardiography. Physical examination, laboratory testing, and radiographic imaging aid only in the exclusion of alternative diagnoses. Cardiac stress testing may be required in certain patient populations. A reported clinical response to antacids should not be used to make the presumptive diagnosis of GERD in the emergency department (ED).

**TREATMENT**

Lifestyle modifications may reduce symptoms by decreasing the frequency and amount of gastric reflux. Examples of low-cost, low-risk recommendations are summarized in the Patient Teaching Tips box in this section of the chapter.8

Acid-suppressive medications are indicated in patients without adequate relief from lifestyle modifications. The two most commonly used drugs for the treatment of GERD are H2 receptor antagonists (H2RAs) and proton pump inhibitors (PPIs). Acid-suppressive medications do not prevent reflux; they improve GERD symptoms by suppressing production of acid in the stomach and raising the pH of the refluxed material.

H2RAs have similar efficacy with equivalent dosing schedules (Table 31.1). These agents have previously been recommended as first-line therapy; however, a Cochrane review suggests that PPIs relieve heartburn better than H2RAs do in patients treated without specific diagnostic testing.9 These medications should be used for 2 to 4 weeks before any reassessment of symptoms. Recurrence is a common problem in patients with reflux, and therefore many patients require long-term maintenance therapy.

Success rates with PPIs approach 90%, and all agents have equal efficacy at appropriate doses (Table 31.2). Once-daily dosing before breakfast is sufficient for the control of mild to moderate GERD; twice-daily dosing should be considered for those with severe or refractory symptoms. Gastroprokinetic agents (cisapride) and coating agents (sucralfate) are less effective than PPIs but may be useful in selected patients as second-line agents.

**NEXT STEPS IN CARE**

Admission to an inpatient or observation unit is indicated when life-threatening causes of the patient’s complaints cannot be excluded in the ED. The vast majority of patients in whom clinically suspected GERD is diagnosed in the ED can be sent home with outpatient follow-up. Emergency physicians can initiate presumptive acid-suppressive therapy;

**Patient Teaching Tips**

**Dietary Avoidance**

- Avoid foods that are acidic
  - Citrus foods
  - Tomatoes
  - Spicy foods
  - Carbonated beverages

- Avoid foods that cause reflux
  - Fatty foods
  - Coffee, tea, and caffeinated beverages
  - Chocolate
  - Peppermint

**Lifestyle Modifications**

- Smoking cessation
- Weight reduction
- Reduction in meal size
- Reduction in alcohol consumption
- Elevation of the head of the bed
- No eating within 3 hours of bedtime
however, patients must understand the need for follow-up for confirmation of the diagnosis and additional management.

Further diagnostic evaluation, including endoscopy, pH monitoring, manometry, and referral to a gastroenterologist, may be indicated for patients with persistent symptoms. Patients with known reflux esophagitis should be admitted to the hospital for suspected esophageal perforation, significant bleeding, obstruction, volume depletion, or intractable pain. Emergency upper endoscopy is indicated if life-threatening complications are suspected in patients demonstrating dysphagia, odynophagia, upper gastrointestinal bleeding, or weight loss.10

### INFECTIOUS ESOPHAGITIS

#### EPIDEMIOLOGY

Infection of the esophageal mucosa, known as infectious esophagitis, may result from a variety of organisms in an immunocompromised host. Esophageal infections are more commonly observed in patients with acquired immunodeficiency syndrome, cancer, neutropenia, or diabetes mellitus or in those taking chronic immunosuppressive medications, especially corticosteroids.11 Candida species are by far the most common cause of infectious esophagitis, although cytomegalovirus (CMV), varicella-zoster virus, and herpes simplex virus (HSV) represent common viral causes of the condition.12

#### PATHOPHYSIOLOGY

Infectious esophagitis results from direct invasion of the infectious agent into esophageal tissue. Immunosuppression from any condition can lead to esophageal infections, although patients infected with advanced human immunodeficiency virus and those with lymphoma and leukemia receiving chemotherapy are at highest risk. Prevention of adherence of esophageal pathogens is an important pathophysiologic defense. Impairment of salivation, impairment of esophageal motility, and reduction in gastric acid production can result in opportunistic infections. Injury to the esophageal mucosa from radiation treatment also increases the risk for infection.12

#### PRESENTING SIGNS AND SYMPTOMS

Candidal esophagitis may be manifested as retrosternal pain, dysphagia, or odynophagia. Other symptoms of esophageal candidiasis are nausea, vomiting, fever, abdominal pain, and anorexia. Oral candidiasis (thrush) is not consistently present in patients with endoscopically confirmed candidal esophagitis. Systemic candidal infections may be seen in cases of significant immunosuppression.

HSV esophagitis is manifested as severe odynophagia, dysphagia, nausea, and vomiting. Oropharyngeal ulcerations and white exudates may indicate HSV infection, although oral lesions are neither sensitive nor specific enough to confirm a definitive diagnosis. HSV esophagitis is frequently severe enough to warrant admission for pain control.

#### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Pain or difficulty swallowing is the hallmark of infectious esophagitis; however, many infections may be asymptomatic or have other associated symptoms. Infectious esophagitis should be considered in immunocompromised patients at risk for opportunistic infections. Given the similar spectrum of signs and symptoms, the differential diagnosis of infectious esophagitis includes the same life threats and serious conditions as reflux esophagitis (see Box 31.2).

#### TREATMENT

In patients in whom infectious esophagitis is suspected, empiric treatment of Candida should be initiated. Esophageal candidiasis requires systemic therapy; topical agents are ineffective. Treatment should begin with fluconazole, 100 to 200 mg daily for 2 to 3 weeks; this regimen is efficacious in 80% to 90% of cases. Esophagitis caused by HSV or CMV needs to be confirmed by biopsy and requires systemic antiviral therapy.

#### NEXT STEPS IN CARE

All cases of infectious esophagitis require consultation with infectious disease and gastroenterology specialists to arrange for expedited testing. Patients with significant symptoms in whom infectious esophagitis is suspected need to be admitted to facilitate diagnosis by upper endoscopy. Suspicion of a systemic infection mandates hospital admission.

Biopsies, cultures, and other related testing may be deferred to the inpatient setting. Outpatient management should be reserved for stable patients for whom urgent follow-up has been scheduled with a primary care or subspecialty physician. Treatment failures with fluconazole will probably be the result of either primary infection or coinfection with HSV, CMV, or other viral or bacterial organisms.

PILL ESOPHAGITIS AND CAUSTIC ESOPHAGEAL INJURY

EPIDEMIOLOGY

Pill esophagitis refers to damage to the esophageal mucosa by prolonged direct contact with a caustic agent. A variety of medications have been reported to cause esophageal injury, but the majority of cases involve potassium chloride, quinidine, emepronium bromide (Cetiprin), alendronate sodium (Fosamax), nonsteroidal antiinflammatory drugs, vitamin supplements, or antibiotics. Caustic injury to the esophagus results from the accidental or intentional ingestion of extremely acidic or alkaline agents. Caustic injuries are reported to have an estimated incidence of approximately 10,000 cases per year in the United States.14

PATHOPHYSIOLOGY

Bisphosphonates, a notorious cause of pill esophagitis, cause esophageal injury as a result of nonspecific irritation secondary to contact between the pill and the esophageal mucosa. Following ingestion of a caustic substance, the extent of tissue injury and destruction depends on the physical properties and concentration of the ingested agent, the duration of contact, and the amount ingested. Acidic agents produce coagulation necrosis, which creates burns that limit tissue damage. In contrast, alkaline agents produce liquefaction necrosis, which continues to cause tissue damage as long as the offending substance is in contact with the tissue. Esophageal erosions from pill irritation or caustic ingestion can progress to ulcerations and ultimately to perforation in rare cases. The most concerning long-term complications from damaging caustic ingestions are stricture formation and esophageal malignant transformation.

PRESENTING SIGNS AND SYMPTOMS

Symptoms begin shortly after the patient takes the medication or ingests the agent and include nausea, vomiting, severe retrosternal pain, odynophagia, and difficulty handling secretions. Patients are more likely to experience pill esophagitis if they take their medications with minimal fluid, while recumbent, or immediately before bedtime. Ingestion of strong acidic or strong alkaline substances can produce serious injury and significant symptoms, whereas agents such as bleach, detergent, and ammonia cause only mild injury and symptoms.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

A presumptive diagnosis of pill esophagitis or caustic ingestion can be made when the history and the signs and symptoms are clear. For confusing or atypical findings, the same differential diagnosis for GERD listed in Box 31.2 must be investigated. If other esophageal disease is suspected (e.g., strictures, perforation), additional testing is indicated. Upper endoscopy is the most sensitive method of detecting pill-induced mucosal injury and assessing the extent of caustic injury following the ingestion of a corrosive agent. The timing of endoscopy is still under debate, but most medical centers perform the procedure early to define the extent of esophageal injury.13

TREATMENT

Analgesics and coating agents may provide temporary symptomatic relief of pill esophagitis. Conversion of the offending medication to a liquid preparation often prevents recurrence. Another preventive measure is drinking water before and with medication, preferably in a fully upright position. Frequently, the use of sucralfate may promote healing of the injured mucosa. Induced emesis, gastric lavage, and charcoal are not indicated in the setting of caustic ingestion. Dilution of the substance with water is a reasonable treatment option. Deferment of oral intake, aggressive supportive management, and high vigilance for esophageal perforation are necessary in the setting of serious esophageal damage.

NEXT STEPS IN CARE

Most patients with pill esophagitis may be discharged with analgesics and follow-up. Patients unable to swallow secondary to severe odynophagia or a suspected stricture must be admitted for intravenous hydration, pain control, and gastroenterology consultation. Most patients with serious caustic ingestions will need admission to the hospital for emergency endoscopy. The ultimate disposition of the patient depends on the extent of injury.

ESOPHAGEAL FOREIGN BODIES AND FOOD IMPACTION

EPIDEMIOLOGY

Ingestion of a foreign body and food impaction are relatively common causes of ED visits. Esophageal foreign bodies are most commonly seen in children (80%) between 1 and 4 years of age.15 A significant proportion of adults with esophageal foreign bodies are prisoners, suffer from psychiatric illness, or have recurrent episodes of intentional foreign body ingestion. A wide range of ingested foreign bodies have been reported, and they can be conceptually grouped into the most threatening and most common foreign bodies (Box 31.3). The most dangerous esophageal foreign body in children is a disc (button) battery, which has shown a greater than sixfold increase in serious complication or fatalities from 1985 to 2009.16

PATHOPHYSIOLOGY

Foreign objects tend to lodge in one of four areas of anatomic narrowing in the esophagus: the upper esophageal sphincter, the aortic crossover, the left mainstem bronchus crossover,
and the LES. The upper sphincter is the most common site of impaction in children (75%), and the LES is the most common location in adults (70%). Foreign bodies in the upper esophageal sphincter may compress the airway and cause respiratory distress. Erosions from a foreign body or perforation from an ingested sharp object can result in mediastinitis and injury to adjacent structures such as the great vessels and trachea.

Although food impaction can occur in patients with a normal esophagus, both adult and pediatric patients often have an underlying esophageal abnormality. Abnormal areas of esophageal narrowing that predispose individuals to foreign body impaction include strictures, malignancies, dysmotility disorders (achalasia), and scleroderma.8,9

**PRESENTING SIGNS AND SYMPTOMS**

Children and adults with esophageal foreign bodies may have an acute onset of drooling or respiratory distress. Other common symptoms associated with esophageal foreign bodies are retrosternal pain, dysphagia, coughing, gagging, wheezing, anorexia, and refusal to drink fluids. Unwitnessed ingestions account for approximately 40% of esophageal foreign bodies in children.2 Parental suspicion of an ingested object may prompt ED evaluation, even in an asymptomatic child. The vast majority of ingested objects will pass spontaneously; however, dangerous objects such as button batteries and sharp objects must be removed, even in asymptomatic patients.

Adults with esophageal impaction after a known ingestion generally have symptoms of dysphagia, foreign body sensation, chest pain, and vomiting. Impaction commonly involves a large, poorly chewed food bolus such as a piece of meat. Patients with complete obstruction of the esophagus are unable to swallow, drool, and have episodes of retching in an attempt to dislodge the obstruction.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Box 31.4 lists the differential diagnosis for esophageal foreign bodies. If a report of an ingested object is obtained from the patient, the diagnostic considerations are relatively straightforward. In both children and adults in whom a history of ingestion is unclear, more comprehensive assessment of the patient’s symptoms to include cardiac ischemia, infectious causes, and motility disorders should be considered. A high index of suspicion for an ingested foreign object must be maintained in children younger than 4 years because the history of ingestion is often absent and verbalization of symptoms is problematic.

**TREATMENT**

A diagnostic algorithm for the evaluation of a suspected esophageal foreign body is presented in Figure 31.1. Foreign bodies found to be in the stomach will probably pass through the remainder of the gastrointestinal tract without intervention. Oral fluid challenges should be attempted when a foreign body is not identified on plain radiographs. Inability to tolerate fluids should prompt further evaluation with computed tomography or endoscopy.

Endoscopy is the preferred method for definitively removing or advancing an esophageal foreign body, especially when the presence or nature of the foreign body is uncertain. Endoscopy allows direct visualization of sharp or otherwise dangerous foreign objects that pose a significant risk for perforation. Although endoscopy is costly and requires the availability of a specialty consultant, this technique can be performed in the ED and may prevent hospital admission.

Foreign bodies may also be guided into the stomach by bougienage, or advancement of a rubber dilator from the oropharynx into the esophagus. Removal of the foreign body may be attempted by passing a urinary catheter distal to the object under fluoroscopic guidance, inflating the balloon, and using the inflated distal catheter to withdraw the object. Foreign body advancement via bougienage and removal with a urinary catheter should be attempted only by skilled operators; complications include airway compromise and esophageal perforation. When reserved for relatively low-risk foreign bodies such as coins, these techniques have reported success rates of approximately 95% without serious complications.20 It should be recognized that removal of foreign bodies by bougienage is considered by many to be quite controversial.

Glucagon, nitroglycerin, and benzodiazepines have commonly been used to relax the LES and promote advancement of the foreign body in the esophagus. No convincing trials,
Patients with dangerous foreign bodies such as disc batteries and sharp objects should undergo emergency endoscopy. The opportunity for safe removal of an esophageal button battery is approximately 2 hours, with delay in diagnosis or removal of the battery contributing to catastrophic outcomes. Patients with unresolved but low-risk foreign bodies should be referred however, have demonstrated that these medications improve the resolution of esophageal foreign bodies. Glucagon commonly causes vomiting, which poses an increased risk for aspiration. Use of these medications often serves only to delay involvement of a consultant for definitive removal of the foreign body. The addition of a gas-forming agent or oral meat tenderizer is also not recommended because of an increased risk for perforation.

Fig. 31.1 Diagnostic algorithm for the evaluation of a suspected esophageal foreign body. CT, Computed tomography; IV, intravenous line; Lat, lateral; LES, lower esophageal sphincter; PA, posteroanterior.
for endoscopy within 24 hours if they are able to tolerate oral fluids. Stable patients with nondangerous foreign bodies can be observed for several hours without harm.

Adults with foreign bodies that resolve with observation should be referred for outpatient evaluation of potential structural or neuromuscular diseases of the esophagus. Children with resolved foreign bodies may be discharged for follow-up with a primary care provider. A swallowed coin in the esophagus (Fig. 31.2) and a fishbone in the hypopharynx (Fig. 31.3) are common esophageal foreign bodies.

**ESOPHAGEAL PERFORATION**

**EPIDEMIOLOGY**

Esophageal perforation is defined as a transmural communication between the upper gastrointestinal tract and the mediastinum. Perforation leads to a rapidly progressive chemical and infectious mediastinitis that can result in sepsis and death. Iatrogenic perforations may occur at any anatomic location and account for up to 60% of all cases; they carry a mortality rate of approximately 20%.²²

Boerhaave syndrome, or spontaneous esophageal perforation, is most commonly the result of forceful retching or vomiting. Other conditions associated with this syndrome are childbirth, coughing, seizures, asthma exacerbations, and the Valsalva maneuver. Even with treatment, this entity has a mortality rate approaching 30%.²³

**PATHOPHYSIOLOGY**

Esophageal perforations occur as a result of injury to the esophageal wall through direct trauma, tumor growth, or caustic erosion. Most cases of Boerhaave syndrome occur in the left posterolateral portion of the esophagus because of the relatively thin muscularis layer and lack of external structural support in this area.

**PRESENTING SIGNS AND SYMPTOMS**

Esophageal perforation is classically accompanied by mild, nonspecific symptoms that lead to misdiagnosis initially in more than half the patients. Pain is the initial symptom in 70% to 90% of cases, although variability in location makes this symptom difficult to interpret. Pain may be felt in the chest, neck, abdomen, or upper part of the back and may be increased with deep breathing or swallowing.²⁴ Other common symptoms are dyspnea, odynophagia, vomiting, and hematemesis.

**RED FLAGS**

- Esophageal Perforation
  - Dyspnea
  - Sepsis
  - Hematemesis
  - Subcutaneous emphysema

---

**Fig. 31.2** A and B, Chest radiographs demonstrating a coin in the esophagus (coronal lie).

**Fig. 31.3** Computed tomography scan of the esophagus demonstrating an impacted foreign body: a fish bone was impacted in the hypopharynx. (Courtesy of E. Wolf, MD, Montefiore Medical Center, Bronx, NY.)
The clinical findings depend on the location of the perforation and the delay between perforation and evaluation. Delayed evaluation for esophageal perforation will be complicated by findings of septic shock: fever, tachypnea, tachycardia, and hypotension. Physical examination may reveal subcutaneous emphysema of the neck or upper part of the chest in approximately 60% of patients. Hamman crunch is a classic but uncommon auscultatory finding attributed to mediastinal emphysema.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Given the variable findings in patients with esophageal perforation, misdiagnosis and delay in treatment are unfortunately typical. The initial symptoms, like many other esophageal disorders, can be consistent with myocardial infarction, peptic ulcer disease, pancreatitis, aortic dissection, and pneumothorax. A diagnostic algorithm for the evaluation of suspected esophageal perforation is presented in Figure 31.4. Chest radiographs often demonstrate nonspecific findings such as pleural effusions or perhaps pneumomediastinum. Contrast-enhanced fluoroscopic swallow studies should be performed in patients who can sit erect and tolerate liquids (Figs. 31.5 and 31.6). Computed tomography of the esophagus is an alternative method of confirming the presence but not necessarily the location of a suspected perforation (Fig. 31.7). Again, pleural effusions and pneumomediastinum are common findings.

TREATMENT

Severe sepsis can develop quickly in patients with esophageal perforation, especially those with a delayed diagnosis or evaluation. Aggressive resuscitation with early surgical consultation is mandatory. The ED practitioner should obtain intravenous access and administer broad-spectrum antibiotics effective against gram-positive, gram-negative, and anaerobic organisms. Acceptable empiric regimens include piperacillin/tazobactam (Zosyn), 3.375 g intravenously (IV), or ceftiraxone, 2 g IV, plus metronidazole (Flagyl), 500 mg IV, or clindamycin, 900 mg IV. A nasogastric tube should be inserted to decompress the stomach and reduce further mediastinal contamination (see also Chapter 46).

Early surgical intervention improves the odds of survival in patients with esophageal rupture, with the best results achieved if primary closure is performed within 24 hours. An increasing body of evidence suggests that esophageal stenting and nonoperative management may be useful in selected cases. In nonoperative management, drainage of pleural fluid collections with tube thoracostomy, continued nasogastric suction, and bypass of the esophagus with gastric tube placement or total parenteral nutrition are common adjunctive therapies.

NEXT STEPS IN CARE

All patients in whom the diagnosis of esophageal perforation is suspected or confirmed should be admitted to a monitored or intensive care unit under the care of a thoracic surgeon or a general surgeon experienced in esophageal repair.

ESOPHAGEAL MOTILITY DISORDERS

EPIDEMIOLOGY

Esophageal motility disorders represent a spectrum of disorders caused by abnormal coordination of peristalsis and relaxation of the esophageal sphincters. Effective characterization of these disorders has only recently been achieved after manometric and fluoroscopic measurements became more widely available. Five distinct disorders have been described: achalasia, diffuse esophageal spasm, nutcracker esophagus, ineffective esophageal motility, and disorders of LES relaxation. The best-defined esophageal motility disorder, achalasia, is rare with an incidence of 1 per 100,000 population.

PATHOPHYSIOLOGY

Esophageal motility disorders result from a number of different pathophysiologic mechanisms that result in functional aberrations of the esophagus. Anatomically and radiographically, the esophagus usually appears normal. Achalasia results from degeneration of the plexus myentericus, which causes an impairment in relaxation of the LES and abnormal peristaltic contractions of the esophagus. The other motility disorders are less well understood and are believed to be caused by an impairment in the normally coordinated muscle contractions that occur with swallowing.

PRESENTING SIGNS AND SYMPTOMS

Dysphagia is the hallmark symptom of esophageal motility disorders. Dysphagia occurs with both solid foods and liquids, in contrast to causes of mechanical obstruction, which are
CHAPTER 31  ■  ESOPHAGEAL DISORDERS

Fig. 31.4  Diagnostic algorithm for the evaluation of suspected esophageal perforation.  CT, Computed tomography;  ECG, electrocardiogram;  ICU, intensive care unit;  IV, intravenous line;  Neg, negative;  Pos, positive.

typically associated with difficulties only with solids. Similar to other esophageal disorders, the associated symptoms of heartburn, odynophagia, chest pain, and dyspnea are common in esophageal motility disorders. Regurgitation of previously swallowed, undigested food material is typical of advanced achalasia. Patients with diffuse esophageal spasm or nutcracker esophagus (resulting from disordered propagation of peristalsis) can have severe chest pain and dysphagia mimicking cardiac ischemia.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Esophageal motility disorders can be diagnosed only with manometric measurements of the esophagus. Emergency medicine physicians need to be aware that esophageal motility disorders exist and can be suspected clinically; however, they cannot be definitively diagnosed in the ED. Other life-threatening and serious causes of dysphagia, chest pain, and heartburn should be considered first. The same considerations for the broad differential diagnosis presented in Box 31.2 should be investigated.

TREATMENT

Therapies for esophageal motility disorders are as poorly defined as the disorders themselves. Treatment options for achalasia focus on reduction of LES pressure. Botulinum toxin injections, myotomy, and dilation of the LES have been use to treat achalasia with mixed success. Smooth muscle relaxant medications, such as calcium channel blockers, and benzodiazepines have also been used anecdotally to treat achalasia and other esophageal motility disorders without clear benefit.28

NEXT STEPS IN CARE

Patients with cardiac risk factors and no known diagnosis of an esophageal motility disorder are often admitted to the hospital for observation. Most patients can be discharged from the ED for follow-up with a primary care physician in the absence of serious or concerning symptoms. Patients with persistent symptoms will ultimately need to be referred to a specialist in esophageal motility disorders for manometric testing.

REFERENCES

Dyspepsia refers to chronic or recurrent pain of gastroduodenal origin centered in the upper part of the abdomen. Dyspepsia affects 25% to 40% of people in industrialized nations, who regularly experience pain accompanied by any or all of the following associated symptoms: bloating, fullness, early satiety, nausea, anorexia, heartburn, regurgitation, and belching. Patients experiencing dyspepsia with endoscopic evidence of gastric mucosal inflammation are said to have gastritis, and those with ulcerations of the stomach or duodenal lining have peptic ulcer disease (PUD). Dyspepsia, gastritis, PUD, and the long-term complication gastric carcinoma represent a progressive spectrum of illness.

Dyspepsia accounts for 2% to 5% of annual visits to primary care physicians in the United States, and more than 1 billion health care dollars is spent on prescription medications for this disorder each year. PUD chronically affects large portions of the U.S. population and leads to impressive health expenditures because many affected patients leave the workforce. More than 7000 American deaths are attributed to PUD each year, largely as a result of perforation and gastrointestinal bleeding.

In up to 60% of patients in whom dyspepsia is diagnosed, the results of endoscopic evaluation are nondiagnostic. The remaining 40% generally have one of three causative diagnoses: PUD, gastroesophageal reflux disease, or gastric cancer. The broad differential diagnosis of recognized causes of PUD is summarized in Table 32.1.

Duodenal ulcers occur three to four times more frequently than gastric ulcers worldwide, with men being affected more commonly than women for both ulcer types. The male-tofemale ratio for duodenal ulcer (4:1) is higher than that for gastric ulcer (2:1). Such distributions are observed mainly in the developing countries of Africa and Asia. In westernized societies, the distribution of both ulcer types between the sexes has become more equal over the past few decades, although the mechanisms underlying these epidemiologic changes are unknown.

PUD is the most common cause of upper GI bleeding in the United States and accounts for 27% to 40% of all cases. Patients with PUD who are at highest risk for upper GI bleeding include alcoholics, chronic users of nonsteroidal antiinflammatory drugs (NSAIDs), and patients with renal dysfunction.

The stomach is anatomically subdivided into three parts: the fundus, the corpus (body), and the antrum (Fig. 32.1). This subdivision reflects differences in function. The stomach functions as a reservoir for ingested meals, as well as the site of food agitation with gastric secretions—the first step in digestion (see Fig. 32.1). The acidic fluid is secreted by parietal cells in the fundus and body of the stomach under the control of hormones secreted by endocrine cells in the antrum. Acid secretion is controlled by the complex interaction of gastrin from G cells and histamine from...
and 60% of gastric ulcers has led to a paradigm shift in the understanding and management of PUD.6

**INFECTIONAL CAUSES**

*Helico-bacter pylori*, a gram-negative, helix-shaped bacterium, infects at least 50% of the population worldwide and is recognized as an important risk factor for the development of PUD and ultimately gastric adenocarcinoma and lymphoma. Infection is probably acquired in childhood and, in the absence of antimicrobial therapy, persists for life with an estimated lifetime risk for PUD of 15%.7-9 Risk factors for the acquisition of *H. pylori* include sharing of a bed in childhood, large number of siblings, lower socioeconomic status, and lack of a fixed hot water supply.6,19 Although it is still unclear whether transmission occurs person to person, three different mechanisms for such transmission have been postulated: fecal-oral, through saliva, and by vomitus.6,9

*H. pylori* causes acute dyspepsia characterized by epigastric pain, nausea, vomiting, and halitosis. Symptoms usually last several weeks and then disappear, although the organism loiters within the stomach. Gastritis persists throughout life in various locations; it shifts from an antrum-predominant pattern to a corpus-predominant pattern or pangastritis.10 The chronic phase of the disease is usually benign, but in susceptible individuals, complications such as gastric or duodenal ulcers may arise.

If sufficiently virulent, *H. pylori* gastritis leads to destruction of the gastric mucosa, which can ultimately result in the development of intestinal metaplasia or eventually carcinoma. The rate of gastric acid secretion declines, thereby fostering conditions beneficial to colonization of the gastric lumen by fecal organisms. *H. pylori* eventually disappears because the organism is ill-equipped to compete with a growing number of other organisms and is unable to thrive on metaplastic cells in the absence of hyperacidic conditions. Despite its eventual demise, the initial invasion of the stomach lumen by *H. pylori*...
incites conditions that favor the evolution of non-cardia–associated gastric cancer.\(^6\)

Though most common, \(H.\ pylori\) is not the sole infectious cause of PUD. *Helicobacter heilmannii*, another spiral non-spirchetal bacterium transmitted via domestic animals and monkeys, has been associated with \(H.\ pylori\)–negative duodenal ulcers. It is much rarer than \(H.\ pylori\), is less pathogenic, and can easily be differentiated by routine histology. Treatment strategies similar to those for \(H.\ pylori\) are successful in eradicating this organism.\(^1^9\)

Additional infectious agents include cytomegalovirus (CMV), herpes simplex virus type 1, (HSV-1) and syphilis. CMV was first associated with peptic ulcers in renal transplant recipients and is the only organism to be significantly associated with peptic ulceration in persons positive for human immunodeficiency virus. The ulcers in these patients are usually gastric and numerous. The diagnosis is confirmed by the finding of intranuclear inclusion bodies or CMV DNA (or both) in the gastric mucosa on biopsy specimens taken from the base of the ulcer. HSV-1–induced ulcers are generally located in the antrum and often occur in immunocompetent individuals.\(^1^0\)

### DRUG-RELATED CAUSES

In the absence of \(H.\ pylori\), use of NSAIDs is the cause of PUD in up to 60% of patients.\(^1^6\) Because gastroduodenal damage does not occur in all patients taking NSAIDs, it is important to identify those at increased risk (Box 32.1). Factors associated with higher rates of NSAID-related GI complications are a previous history of PUD or hemorrhage, age older than 65 years, prolonged use of high-dose NSAIDs, use of more than one NSAID, concomitant use of corticosteroids or anticoagulants, and serious comorbid illness such as cardiovascular, renal, or hepatic impairment, diabetes, or hypertension.\(^1^7\) Many other drugs are associated with PUD and are listed in Box 32.2.

Crack cocaine and methamphetamine have been linked to PUD, as well as a higher rate of gastric perforation thought to be secondary to vasoconstriction and resulting local tissue ischemia. Additionally, tobacco and alcohol can further precipitate gastritis and PUD.\(^1^1\)

### ZOLLINGER-ELLISON SYNDROME

Zollinger-Ellison syndrome (ZES) is an uncommon cause of PUD but should be considered in patients with refractory, atypically located, or numerous ulcers, especially in the absence of \(H.\ pylori\) or NSAID use.\(^1^0,1^2\) The ulcers in patients with ZES are caused by a gastrin-secreting tumor, or gastrinoma.

The incidence of ZES in the United States ranges from 0.1% to 1% in patients with PUD. The most common functional pancreatic tumors in patients with multiple endocrine neoplasia type 1 (MEN-1) are gastrinomas, and approximately 20% of patients with ZES also have MEN-1. The mean age at diagnosis is 50 years, but patients with ZES range in age from 7 to 90 years. Patients with both MEN-1 and ZES become symptomatic at an earlier age, with PUD usually developing in the third decade of life. The male-to-female ratio of patients with ZES ranges from 2:1 to 3:2.\(^1^0,1^2\)

Patients with ZES commonly have symptoms of PUD such as epigastric pain, nausea, and vomiting. Alternatively, severe diarrhea may be the only symptom. Perforated ulcer remains a common complication; approximately 7% of patients with ZES are initially seen with perforation of the jejunum.\(^1^2\)

Evaluation for ZES includes measurement of fasting serum gastrin and basal gastric acid secretion with a secretin stimulation test. Imaging fails to demonstrate the tumor in up to 50% of cases; nonetheless, computed tomography, magnetic resonance imaging, radionuclide octreotide scanning, endoscopic ultrasonography, and the selective arterial secretin injection test are recommended for potential localization.\(^1^2\)

All patients with sporadic gastrinoma who have resectable metastatic disease should undergo exploratory laparotomy for potential curative resection. Surgery may be the most effective treatment of metastatic gastrinoma if the tumor can be excised completely.

### IDIOPATHIC ULCERS

Once all known causes are excluded, a group of peptic ulcers remain that are then considered idiopathic. The etiology of idiopathic PUD is poorly understood but is thought to include a genetic predisposition, altered acid secretion, rapid gastric emptying, defective mucosal defense mechanisms, psychologic stress, and smoking.\(^1^9\) Management of idiopathic peptic ulcers is challenging because these ulcers are more resistant to standard therapy and are associated with more frequent complications. Patients who relapse may require long-term maintenance proton pump inhibitor (PPI) therapy.\(^1^0\)
Dyspepsia refers to a group of symptoms attributed to various pathologic conditions of the upper GI tract, including epigastic pain, bloating, nausea, anorexia, fullness, early satiety, regurgitation, and belching.13,14

Classically, duodenal ulcer pain is described as a gnawing, hungerlike pain in the epigastrium with occasional but generally mild radiation to the back. The pain typically improves just after eating and worsens 2 to 5 hours after meals. Duodenal ulcer pain tends to be more pronounced in the early morning hours (11 PM to 2 AM) because of peak acid levels in the stomach at that time. Peptic ulcers have similar findings, although classically the pain intensifies with food intake, in contrast to duodenal ulcers. The pain in patients with untreated PUD tends to occur in clusters, with intermittent pain lasting weeks to months and asymptomatic periods between flares.

Several red flags should be considered when taking a history from patients with dyspepsia. These red flags increase the risk for gastric carcinoma as the cause of the patient's symptoms and include age older than 45 years, unintentional weight loss, persistent vomiting, progressive dysphagia, odynophagia, unexplained anemia or iron deficiency, hematemesis, palpable abdominal mass, family history of GI cancer, and previous gastric surgery or jaundice (see the Red Flags box).14

Several ethnic groups also have a higher disease prevalence, including Afro-Caribbean, Hispanic, Asian, and Native American populations.14,16,17

Patients should be screened for historical features suggestive of disease progression and complications, including perforation, pyloric outlet obstruction, and hemorrhage. A change in the character of pain from vague, epigastric discomfort to severe, localized pain, especially with radiation to the back, can indicate perforation. Additionally, unremitting pain that was previously well controlled with food or antacids also suggests progression of disease.

Acute, severe, diffuse abdominal pain with or without referred shoulder pain may indicate recent perforation. Although nausea can be associated with dyspepsia, vomiting is less common; early pyloric stenosis should be considered if vomiting is a prominent feature.

Hemorrhage from upper GI bleeding may be manifested as syncope, melena, or hematemesis; consequently, GI bleeding should be considered in the differential diagnosis of patients with vague presyncope or syncope, especially those with risk factors for PUD.

Unstable vital signs suggest the possibility of massive GI bleeding in the setting of PUD. The overall appearance of the patient may be noteworthy for cachexia, which is concerning for underlying malignancy. Skin should be examined for jaundice and pallor, which is concerning for anemia.

Abdominal findings in the setting of uncomplicated PUD are generally normal or may be significant only for mild epigastric pain. Peritoneal findings suggest perforation.18

The primary goal of emergency department (ED) evaluation of dyspepsia is to localize the source of the symptoms to the upper GI tract by excluding other life-threatening diagnoses, most notably acute coronary syndrome. Atypical acute coronary syndrome may have similar manifestations as PUD, especially in elderly, diabetic, and female patients. An electrocardiogram and cardiac markers should be evaluated in all ED patients with a new onset of dyspepsia.

Other organ-specific conditions in the differential diagnosis include pulmonary disease (lower lobe pneumonia, embolism), pancreatitis, biliary disease, inflammatory bowel disease, irritable bowel syndrome, gastroparesis, mesenteric ischemia, and abdominal wall pathology, including abscess, rectus hematomas, or musculoskeletal pain. Systemic and metabolic diseases that should be considered include sarcoidosis, thyroid disease, parathyroid disease, hyperkalemia, and hypercalcemia. The broad differential diagnosis of dyspepsia is summarized in Table 32.1.

A rare though serious infectious source of epigastric pain is phlegmonous gastritis caused by a bacterial infection of the stomach. This infection of mixed gram-positive cocci and gram-negative rods occurs in the setting of previous gastric pathology, including PUD, gastritis, gastric surgery, or carcinoma. These patients are very ill appearing, and treatment includes aggressive resuscitation, early antibiotics, and admission to the intensive care unit.

Although laboratory tests are not required in routine cases of chronic, recurrent dyspepsia, they are necessary in the evaluation of patients with a first episode of dyspepsia or a change in symptoms to exclude complications of disease progression or alternative cardiac, pulmonary, or GI conditions on the differential. A complete blood count, comprehensive metabolic panel, lipase, and cardiac enzymes should be evaluated. Imaging is not generally indicated unless perforation with free air (upright chest radiograph) or biliary disease (right upper quadrant ultrasound) is a concern.

For patients in whom acute coronary syndrome can be excluded in favor of a diagnosis of gastritis or PUD, empiric treatment strategies and referral for diagnostic testing are appropriate.
For acute pain management in the ED, start with oral liquid antacids (e.g., Maalox, 30 to 60 mL orally) mixed with viscous lidocaine, 15 to 20 mL orally. The addition of an anticholinergic, antispasmodic agent such as Donnatal has no role in treatment. H2 blockers may be initiated in the ED, although the onset of action after both oral and parenteral administration of these agents is too slow to provide immediate pain relief. Parenteral H2 blocker therapy (e.g., Pecid, 20 mg intravenously) may be most useful for patients with suspected ZES who will be admitted to the hospital. Parenteral narcotic analgesics should be administered to patients with pain uncontrolled by oral agents or to those in whom perforation or hemorrhage is suspected (i.e., oral medications are contraindicated).

In hemodynamically stable patients whose symptoms are not severe enough to warrant admission, three options are available for the management of dyspepsia not related to NSAIDs. The first option is a single, short-term trial of empiric antiulcer therapy with a PPI in a setting in which the patient has reliable follow-up.19 Cytoprotective agents such as sucralfate suspension may prevent further injury to the gastric mucosa and provide immediate relief of symptoms. Regardless of response, all such trials should be stopped after about 6 weeks and an evaluation performed if symptoms recur; further investigation is warranted earlier if the symptoms do not respond in 2 weeks. The second option is a definitive endoscopic evaluation, especially in patients with red flags by history, physical examination, or laboratory evaluation. The urgency for definitive diagnosis stems from a risk that gastric ulcers harbor malignancy in this population. The third option is noninvasive testing for H. pylori via serum antibody screening followed by outpatient prescription of antibiotics in H. pylori–positive subjects. For most low-risk patients, referral to a primary care physician for H. pylori testing plus initiation of symptomatic PPI therapy in the ED is the preferred option.13,20

Patients with known H. pylori disease who are either treatment naïve or were inadequately treated should start a regimen of either a bismuth-metronidazole-tetracycline combination plus a PPI or a PPI plus clarithromycin and either metronidazole or amoxicillin.21 When H. pylori is a consideration, endoscopy should be delayed for 4 to 8 weeks after discontinuation of antibiotics, PPI, and bismuth so that infection status can be more reliably assessed at biopsy.

Communicate with the patient’s primary provider if serologic testing was performed or empiric therapy for H. pylori was started so that the outpatient provider can arrange further diagnostic evaluation. Additionally, confirm with patients that they understand the treatment plan, the seriousness of the diagnosis, and which lifestyle modifications would aid in healing. Specifically, patients should be educated about the negative effects of smoking, excessive alcohol use, failure to follow up, and noncompliance with medication. Finally, patients should decrease or avoid the use of NSAIDs.19 If NSAID therapy must continue, the addition of a PPI will allow most duodenal and gastric ulcers to heal in timely fashion.10,19 Patients with healed NSAID-induced ulcers are among those at highest risk for further gastroduodenal injury and serious complications such as perforation and bleeding; strict return precautions should be provided for these patients.11

Surgery is rarely necessary given that medical therapies for PUD are so effective. Indications for elective surgical treatment of PUD are (1) protracted and failed medical therapy and (2) suspicion of malignancy.22 For the rare nonhealing benign gastric ulcer, resection is indicated for the management of symptoms and prevention of malignancy. Profuse bleeding was a previous indication for surgery, but endoscopic therapy (whether by electrocautery, heater probe, or injection sclerotherapy) controls bleeding in the majority of cases (Fig. 32.3).22 Surgery is indicated for cases in which bleeding is not controlled with endoscopy or is recurrent.

When surgery is being considered, some well-established risk factors increase the likelihood of a fatal outcome, including the presence of severe comorbid conditions, perforation...
longer than 24 hours in duration, and the presence of hypotension on initial evaluation. Conservative management consisting of nasogastric suction, circulatory support, and antibiotics should be used in elderly patients with these risk factors.\textsuperscript{22}

**SECTION IV GASTROINTESTINAL DISEASES**

**SEQUELAE OF PEPTIC ULCER DISEASE**

**GASTRIC CANCER**

Gastric cancer is the second most common cause of cancer-related death worldwide. It is the third most common cancer in southeastern Europe and South America, and globally it is the fourth most common form of cancer.\textsuperscript{23} In comparison with the rest of the world, Western Europe and the United States have a relatively low incidence of gastric cancer; the highest incidence of gastric cancer is reported in Japan, China, and South America.\textsuperscript{4} Gastric cancer rates remain quite high in some subgroups of African Americans, Hispanics, and Native Americans. In the United States, the mean age at diagnosis is 48 years, and the male-to-female ratio is 1:1.\textsuperscript{23}

Although certain well-established genetic factors predispose one to gastric cancer, such as blood type A, the main causative agents are environmental.\textsuperscript{24} \textit{H. pylori} infection promotes apoptosis in infected cells, thereby starting a metaplastic path of destruction. Inhibition of E cadherin synthesis by \textit{H. pylori} is also associated with the development of gastric cancer. The International Agency for Research on Cancer has classified \textit{H. pylori} as a class I carcinogen, the only bacterial agent with this distinction.\textsuperscript{23}

The prognosis of patients with gastric cancer is poor, with 5-year survival rates of less than 25%.\textsuperscript{23} The improved survival seen in Japanese populations has been attributed to identification of earlier-stage lesions by aggressive screening programs. Such screening programs are less common in the United States. ED patients with suspected dyspepsia and red flags must undergo urgent outpatient follow-up for endoscopic screening for gastric malignancy (**Fig. 32.4**).
GASTRIC OUTLET OBSTRUCTION

Chronic peptic ulcers in either the stomach or duodenum may cause scarring and impair gastric emptying, a condition known as gastric outlet obstruction (Fig. 32.5). In adults, PUD is the major cause of benign gastric outlet obstruction—more than 95% of cases are associated with duodenal or pyloric channel ulceration. Resolution of gastric outlet obstruction after the eradication of *H. pylori* has been demonstrated in several studies. Symptomatic improvement can be seen a few weeks after the start of antimicrobial therapy for *H. pylori*, and the benefits seem to persist on long-term follow-up.25

Treatment of gastric outlet obstruction should start with pharmacologic eradication of *H. pylori*, even when the stenosis is considered to be fibrotic or when some gastric stasis is present. If such noninvasive treatment is unsuccessful, NSAID use may be the underlying cause.25 Dilation or surgery should be reserved for patients who show no response to medical therapy.

ED patients with signs or symptoms of gastric outlet obstruction should be admitted for gastroenterology consultation, hydration, and further management.

KEY POINTS

- Morbidity and mortality from gastrointestinal bleeding increase significantly if aggressive resuscitation is not initiated immediately in the emergency department.\(^1,2\)
- Assessment and management of gastrointestinal bleeding depend on the site of the hemorrhage—that is, whether the bleeding is from an upper or lower gastrointestinal tract source.
- Gastroenterology consultation should be obtained immediately to arrange for diagnostic and therapeutic endoscopy or colonoscopy for cases of active bleeding.
- Causes of gastrointestinal bleeding in children vary considerably with age; most cases are benign and self-limited, although Meckel diverticulum, midgut volvulus, and intussusception can result in massive rectal bleeding.

SCOPE

Demographic risk factors for patients with gastrointestinal (GI) bleeding include older age, male gender, and the use of alcohol, tobacco, aspirin, or nonsteroidal antiinflammatory drugs (NSAIDs).\(^3\) Risk for bleeding is significantly higher in elderly patients who have recently started a regimen of NSAIDs or regular-dose aspirin than in long-term users of these agents.\(^3\) Additional independent risk factors are unmarried status, cardiovascular disease, difficulty performing activities of daily living, use of multiple medications, and use of oral anticoagulants.\(^3\)

Intensive resuscitation in the emergency department (ED) significantly decreases mortality in patients with hematemesis (vomiting blood), hematochezia (red bloody stools), or melena (black tarry stools).\(^2\) Application of the predictive mnemonic BLEED (ongoing bleeding, low systolic blood pressure, elevated prothrombin time, erratic mental status, unstable comorbid disease) at the initial ED evaluation can predict hospital outcomes in patients with acute upper or lower GI hemorrhage.\(^6\) Although the incidence of peptic ulcer bleeding has decreased, the decline in incidence has occurred only in patients younger than 70 years,\(^7\) and mortality from multiorgan failure, cardiopulmonary conditions, or terminal malignancy has remained constant.\(^4\)

Lower GI bleeding (LGIB) afflicts 20 to 27 of every 100,000 persons annually in the United States.\(^8\) The rate of LGIB increases more than 200-fold from the third to the ninth decade of life, with 25% to 35% of all cases occurring in elderly patients. It is one of the common medical emergencies that can become life-threatening in elderly patients.\(^9,10\) Risk stratification for LGIB by Strate et al. has identified seven predictors of severe bleeding: heart rate higher than 100 beats/min, systolic blood pressure lower than 115 mm Hg, syncope, nontender abdominal examination, gross rectal bleeding, aspirin use, and more than two comorbid conditions. Patients with more than three risk factors have an 84% risk for severe bleeding, defined as transfusion of more than 2 units of red blood cells.\(^11,13\)

Pediatric GI bleeding is fairly common worldwide; however, the incidence of severe GI bleeding in U.S. children is very low.\(^14\) LGIB is a more common complaint in the practice of general pediatrics, and it accounts for 10% to 15% of referrals to a pediatric gastroenterologist.\(^15,17\) In most children, bleeding is not life-threatening and ceases spontaneously, with only supportive care being required.\(^16,17\) The age of the child guides the clinician toward specific diagnoses.\(^16,18\)

PATHOPHYSIOLOGY

UPPER GASTROINTESTINAL BLEEDING

Upper GI bleeding (UGIB) is defined as bleeding from a source proximal to the ligament of Treitz, which is located at the junction of the duodenum and jejunum. UGIB accounts for three quarters of cases of GI tract hemorrhage, with duodenal and gastric ulcers being the specific sources in more than half of patients with an upper tract cause.

Hematochezia is generally a symptom of LGIB but may be associated with brisk upper tract hemorrhage. LGIB sources are identified in 11% of patients in whom LGIB was initially suspected.\(^3\) Melena most commonly results from bleeding proximal to the jejunum and should be considered a marker of UGIB.

Variceal hemorrhage is the most serious complication of portal hypertension and occurs in one third of patients with esophageal varices.\(^3\) It is more common in patients with Child B and C cirrhosis.\(^20\) The extent of severe bleeding depends on portal pressure, variceal size, and variceal wall thickness.\(^22\) Esophageal varices should be suspected in any alcoholic with unexplained anemia or obvious GI bleeding.

One study noted a decline in the frequency of peptic ulcer disease in patients with UGIB and reported that the
Gastrointestinal Bleeding

Risks

Use of nonsteroidal antiinflammatory drugs (NSAIDs) may represent an important cause of peptic ulcer disease and ulcer-related hemorrhage in those with upper gastrointestinal bleeding (UGIB). Specifically, use of over-the-counter NSAIDs may represent an important cause of peptic ulcer disease and ulcer-related hemorrhage in those

Although most causes of LGIB in children are self-limited and benign, it is imperative to consider Meckel diverticulum, midgut volvulus, and intussusception in appropriate age groups.

Clinical Presentation

Patients with GI bleeding can be rapidly assessed by their reported volume of blood loss and initial hemodynamic status. Massive hemorrhage is associated with signs or symptoms of hemodynamic instability, including tachycardia (heart rate greater than 100 to 120 beats/min), systolic blood pressure less than 90 to 100 mm Hg, symptomatic orthostasis, syncope, ongoing bright red or maroon hematemesis, transfusion requirements in the first 24 hours, and inability to stabilize the patient.

Vital signs and postural changes should be assessed in patients who appear sufficiently stable. An increase of 20 beats/min or more in pulse or a decrease of 20 mm Hg in systolic blood pressure between the supine and upright positions indicates loss of more than 20% of blood volume in normal adult patients. Tachycardia, low blood pressure, reduced urine output, and conjunctival pallor in patients with GI bleeding are signs that mandate immediate volume replacement. Hypovolemic shock implies at least a 40% loss of blood volume. Note that abnormalities in vital signs, especially postural vital sign, are unreliable in pediatric and elderly patients.

The history should focus on the quantity, frequency, and duration of bleeding (differentiating between melena and hematochezia) to characterize the nature of the GI bleeding. Comorbid status, including other GI disorders, antiplatelet or anticoagulant use, syncope, weight loss, alcohol intake, and cardiovascular disease, should be assessed.

In addition to continuous monitoring of vital signs, physical examination should include assessment of mental status, skin (for jaundice or pallor), and pulmonary and cardiovascular compromise (especially in the elderly because of ischemia from blood loss), as well as a thorough abdominal examination for distention, tenderness, or masses. Digital rectal examination and testing of stool for gross or occult blood should be performed in patients with suspected GI bleeding.

Complaints associated with LGIB include hematochezia or melena, although patients may have additional findings, such as anemia, light-headedness, hypovolemia, weakness, malaise, chest pain, and dyspnea. It is important to note that patients with LGIB may be asymptomatic and have complaints seemingly unrelated to gastrointestinal bleeding (e.g., fatigue, weight loss); dramatic findings consisting of massive rectal bleeding in acutely ill and unstable patients are less common.

Delayed black tarry stools may occur from a source of bleeding in the small bowel or ascending colon and may not be noted by the patient until several days after the bleeding has stopped.

A thorough history and complete physical examination are important for evaluation of a child with GI bleeding. Bright
red blood that coats but is not mixed with stool suggests an anorectal source. Hematochezia indicates bleeding from the distal part of the small bowel or proximal part of the colon. Bloody diarrhea usually suggests colonic bleeding. Current jelly stools are indicative of the vascular congestion and hyperemia seen with intussusception.

Food allergy may lead to GI bleeding from food-induced colitis and could result in dehydration in infants younger than 3 months.17 Anal fissures are common in infants and produce red streaks or spots of blood in the diaper.19 Other causes of dark stool are iron, charcoal, flavored gelatin, red fruits, bismuth, and food dyes. Maternal blood swallowed by neonates during delivery may be diagnosed with the Apt test.17

Differential Diagnosis

The most common causes of UGIB in adults are listed in Box 33.1, and causes of LGIB in adolescents and adults are listed in Box 33.2.

The exact cause of the GI bleeding is less important to the emergency physician (EP) than differentiation between upper and lower tract sources.

An aortoenteric fistula may have developed in a patient with massive LGIB and recent surgery.9

Differential Diagnosis for Pediatric Gastrointestinal Bleeding

Table 33.1 lists the differential diagnosis for UGIB and LGIB according to patient age. Ingestion of maternal blood is the most common cause of suspected GI bleeding in neonates; blood is swallowed during either delivery or breastfeeding (from a fissure in the mother’s breast). Other causes of GI bleeding in neonates include bacterial enteritis, milk protein allergies, intussusception, anal fissures, lymphonodular hyperplasia, and erosions of the esophageal, gastric, and duodenal mucosa.

Mucosal injuries presumably result from a dramatic rise in gastric acid secretion and laxity of the gastric sphincters in infants. Maternal stress in the third trimester has also been proposed to increase maternal gastrin secretion and enhance infantile peptic ulcer formation.

Some drugs have been implicated in neonatal GI bleeding, including NSAIDs, heparin, and tolazoline, which are used for persistent fetal circulation. Indomethacin, administered to

maintain a patent ductus arteriosus in neonates, may cause GI bleeding through intestinal vasoconstriction and platelet dysfunction. Maternal medications can also cross the placenta and incite GI problems in the developing fetus and neonate on delivery. Aspirin, cephalothin, and phenobarbital are well-known causes of coagulation abnormalities in neonates. Stress ulcers in newborns are associated with dexamethasone, which is used for fetal lung maturation.

Rarer causes of GI bleeding in a neonate are volvulus, coagulopathies, arteriovenous malformations, necrotizing enterocolitis (especially in preterm infants), Hirschsprung enterocolitis, and Meckel diverticulitis.14

In infants, GI mucosal lesions and irritations are the most common causes of bleeding and include esophagitis, gastritis, duodenitis, ulcers, colonic polyps, and anorectal disorders. Intussusception is a common and important cause of GI bleeding in this age group. The incidence of intussusception is greatest in infants aged 3 months to 1 year, but it can occur in children up to 5 years of age. Approximately 80% of all cases of intussusception occur in infants younger than 2 years.

Other causes of infantile GI bleeding are infectious diarrhea, midgut volvulus, Meckel diverticulum, arteriovenous malformation, and GI duplication. Rare causes include foreign body ingestion, variceal disease, irritable bowel disease, and acquired thrombocytopenia.

Older children may have any of the preceding conditions, but duodenal ulcer, Mallory-Weiss tear, and nasopharyngeal bleeding are important causes of bleeding in this age group. Less common causes are gastritis or ulcers induced by salicylates or NSAIDs, Henoch-Schönlein purpura, ingestion of caustic substances, hemolytic-uremic syndrome, inflammatory bowel disease, and vasculitis. In adolescents older than 12 years, the most common causes of UGIB are duodenal ulcers, esophagitis, gastritis, and Mallory-Weiss tears.14

**DIAGNOSTIC TESTING**

**NASOGASTRIC ASPIRATION**

Historically, nasogastric aspiration has been used to determine whether the bleeding originated from the upper GI tract in patients with melena—a bloody aspirate confirmed an upper tract source, whereas an aspirate testing negative for blood represented either resolved bleeding or a more distal site of hemorrhage. In some studies, however, nasogastric aspiration was noted to be insensitive for detection of UGIB in patients without active hematemesis, and a negative result provided little information about the cause of the bleeding.10,31 The routine use of gastric aspiration and lavage in patients arriving at the ED with GI bleeding is not supported.32 Aspirates testing positive for blood confirm only that the bleeding is proximal to the pylorus, and patients must undergo endoscopy for further differentiation.

A nasogastric aspirate containing more than 1 L of fresh blood or inability to obtain a clear aspirate through lavage with more than 1500 mL of saline should alert the physician to massive UGIB that requires immediate gastroenterologic or surgical intervention. In patients with frank hematemesis and brisk persistent hematochezia, the information provided by nasogastric aspiration may be lifesaving.33

**UPPER ENDOSCOPY**

Esophagogastrroduodenoscopy (EGD) is now the diagnostic test of choice for establishing the source of UGIB. The overwhelming majority of existing data suggest that early endoscopy is a safe and effective procedure in all risk groups.34,35 Patients without active hematemesis may benefit from immediate upper endoscopy by a gastroenterologist to confirm the site of bleeding rather than undergoing the potential additional discomfort and morbidity associated with placement of a nasogastric tube. Endoscopy is both diagnostic and therapeutic in many cases.36 One study noted that live-view video capsule endoscopy (VCE) accurately identifies high- and low-risk patients in the ED with UGIB. The use of VCE to risk-stratify these patients significantly reduced time to performance of emergency EGD and therapeutic intervention.37

**TAGGED RED BLOOD CELL STUDIES**

An advanced modality for detecting of the source of GI bleeding is radionuclide imaging, such as radioisotopic imaging with technetium Tc 99m sulfur colloid—or technetium pertechnetate–labeled red blood cells. Technetium Tc 99m red blood cell imaging is a useful test in the management of acute GI bleeding, particularly if the bleeding has been occurring for more than 3 hours and other modalities have failed to identify a source. A limitations of this test is poor detection of bleeding in the foregut, with the highest sensitivity noted for bleeding in the colon.38 A technetium Tc 99m sulfur colloid–labeled red blood cell study requires active bleeding at a rate of more than 0.1 mL/min for visualization. Radionuclide imaging has not been widely tested in the ED setting and is still reserved for inpatient use at most institutions.

**ARTERIOGRAPHY**

Angiography is appropriate for initial testing of patients with massive bleeding.39 When the bleeding cannot be identified and controlled by endoscopy, intraoperative enteroscopy or arteriography may help localize the bleeding source and facilitate segmental resection of the bowel.40 Mesenteric angiography can detect bleeding at a rate of 0.5 mL/min or greater.41 Either angiography or angiographic computed tomography may be used to identify aortoenteric fistulas.42,43

Intraarterial injection of vasopressin or other vasoconstrictors at the site of bleeding can control hemorrhage; embolization is an option when intrarterial injection is unsuccessful.42,43

**DISTAL COLONIC IMAGING**

Colonoscopy has high diagnostic yield and a low rate of perforation in patients with LGB. It is best performed after colonic cleansing and in patients with slow bleeding. Proctosigmoidoscopy is used in patients with mild rectal bleeding to determine whether stool above the rectum contains blood. Barium enema is not useful in the acute setting but can be ordered after an acute bleeding episode has resolved.44

The optimal timing for colonoscopic intervention for LGB is still unclear.45 More recent literature defines urgent colonoscopy as taking place within 12 hours.45 Evidence suggests that earlier colonoscopy leads to more diagnostic and therapeutic opportunities35 and reduces hospital length of stay.10,12,45
PROCEDURES

Proper technique for the safe placement and use of nasogastric tubes and gastroesophageal balloon tamponade tubes (e.g., Blakemore-Sengstaken tube) is discussed in Chapter 46.

TREATMENT

Figure 33.1 presents an algorithm for the treatment of GI bleeding. Insert two 18-gauge or larger intravenous lines and administer 0.9% normal saline or lactated Ringer solution on arrival of the patient.41 Quickly evaluate the patient’s hemodynamic status and determine the extent of blood or fluid resuscitation necessary. Standard resuscitative measures for the management of shock should precede or occur in parallel with definitive diagnostic testing. Management should otherwise be directed toward the underlying source of bleeding. Note that in 80% of cases, LGIB spontaneously stops.25

If the patient is hemorrhaging, consult a gastroenterologist and surgeon. Upper endoscopy is the diagnostic and therapeutic procedure of choice for acute UGIB. Surgery is indicated for patients with active bleeding when medical therapy proves
ineffective and continued hemorrhage requires more than 5 units of blood within the first 4 to 6 hours.\textsuperscript{28,29,41,48} Bowel resection may be required for pronounced LGIB.

In the absence of consultants, massive esophageal hemorrhage as a result of variceal bleeding may be temporarily treated with the placement of a gastroesophageal balloon tamponade device (Blakemore-Sengstaken tube). Although this is an uncommon procedure, EPs in remote practice locations should be familiar with the indications for and proper use of such potentially lifesaving devices.

Octreotide acetate is a synthetic analogue of somatostatin that should be administered intravenously to all patients with suspected UGIB from esophageal varices to induce splanchnic vasoconstriction and a reduction in portal hypertension. The loading dose is 50 mcg intravenously, followed by infusion of 25 to 50 mcg/hr for 5 days.

Comorbid condition, such as coagulopathies, hyperkalemia, and cardiac ischemia, should be identified and treated. The EP should consider the administration of fresh frozen plasma, platelets, recombinant factor VIIa (NovoSeven), or desmopressin (DDAVP) as appropriate.

**PATIENT TEACHING TIPS**

Patients should stop drinking alcohol and seek an alcohol cessation program immediately if needed.

Patients who take nonsteroidal antiinflammatory agents should receive concomitant therapy with a proton pump inhibitor.

Patients with gastric ulcers should be reexamined 6 to 8 weeks after the initial bleeding episode.

Patients should maintain daily intake of synthetic bulk-forming agents.

Surveillance colonoscopy should be performed every 3 years in patients with colonic polyps and adenomatous changes or every 5 years in those with hyperplastic polyps.

Mesenteric ischemia results from lack of adequate blood flow to and oxygenation of the mesentery and intestines. The clinical course consists of rapid progression from bowel ischemia to infarction, sepsis, and usually death. The incidence of acute mesenteric ischemia is increasing because of an aging population and the prolonged survivability of patients with severe cardiovascular disease and other significant medical conditions.

Four types of mesenteric ischemia must be considered: acute mesenteric ischemia, nonobstructive mesenteric ischemia (NOMI), mesenteric vein thrombosis, and chronic mesenteric ischemia (or mesenteric angina). The most deadly of these is acute mesenteric ischemia, which results from sudden obstruction of blood flow to the intestines and has a mortality rate approaching 90%.

EPIDEMIOLOGY

Mesenteric ischemia accounts for 0.1% of all hospital admissions and 1% of emergency department (ED) visits for abdominal pain in geriatric patients. Cases of mesenteric vein thrombosis are more difficult to estimate accurately but have been reported at 2 per 100,000 admissions over a period of 20 years at one center.1-3

The overall mortality associated with mesenteric ischemia is between 60% and 93% but rises precipitously once bowel wall infarction has occurred. Mortality remains greatest for acute mesenteric ischemia resulting from obstruction or embolic phenomena. Patients with an early manifestation of NOMI have mortality rates of 50% to 55%, whereas patients with mesenteric vein thrombosis have a 15% mortality at 30 days.1-3 Those affected by chronic mesenteric ischemia have a more prolonged course, are relatively protected by dual blood supply, and present the physician with more numerous chances for intervention.

PATHOPHYSIOLOGY

Any patient with advanced age, atherosclerosis, thromboembolic disease, atrial fibrillation, and processes leading to chronic low-flow states is at risk for the development of arterial mesenteric ischemia (Tables 34.1 and 34.2).1,2,4,5 Mesenteric venous obstruction carries its own separate risk factors, which are similar to those for venous thrombosis anywhere in the body.

Acute mesenteric ischemia is a result of the precipitous onset of hypoperfusion caused by occlusive or nonocclusive obstruction of either arterial or venous blood flow. Acute hypoperfusion occurs in 65% of cases and carries a mortality rate exceeding 60%. Occlusive arterial obstruction is most commonly caused by embolic or thrombotic obstruction of the superior mesenteric artery (SMA). NOMI is often due to vasoconstriction of the splanchic system. Occlusive venous obstruction occurs with thrombosis or segmental strangulation. Mesenteric venous thrombosis is the main cause of mesenteric ischemia in younger patients without cardiovascular disease.

Acute arterial embolism causes a dramatic cessation of blood flow, with rapid progression from ischemia to infarction. As the bowel wall necroses, contamination with intraluminal bacteria leads to peritonitis, sepsis, and toxin-mediated hypotension.

Nonocclusive infarction, which represents 25% of all cases of acute ischemia, is most often caused by splanchnic hypoperfusion and vasoconstriction. Risk factors for nonocclusive disease include advanced age, acute myocardial infarction (AMI), acute cardiac decompensation, and heart failure.

Data from references 1, 2, 4, and 5.

*A plus sign (+) indicates that the factor is a risk for the disease subtype.
†Especially after sclerotherapy.
Diuretics contribute to a decrease in splanchnic perfusion in patients with profound heart disease, whereas medications such as digoxin and alpha-blockers cause regional vasoconstriction and may add to a low-flow state. Cocaine can cause splanchnic vasoconstriction and should be suspected as a cause of mesenteric ischemia in younger patients.

Bowel perfusion is generally preserved during periods of hypotension; therefore, NOMI represents failure of the normal autoregulatory systems.2,6,7 Patients with chronic renal failure may have bowel ischemia after hemodialysis, probably from hypoperfusion, which promotes preferential shunting of blood from the splanchnic circulation to preserve flow to the cardiac and cerebrovascular systems.

Although acute mesenteric vein thrombosis accounts for a small proportion of cases of ischemic bowel disease (5% to 10%), the ease of diagnosis with computed tomography (CT) has allowed identification of a greater number of patients with venous thrombosis. Symptoms are even less specific than those of arterial obstruction and are manifested over a longer period before bowel infarction occurs. Thrombus secondary to hypercoagulable states develops first in the smaller vessels and later progresses into the larger veins; clots associated with cirrhosis, neoplasm, or local injury (operative, trauma) start at the site of obstruction and evolve distally.4

Thrombotic arterial ischemia occurs late in the course of severe mesenteric atherosclerotic disease and involves the three major sources of intestinal blood supply: the celiac artery, the SMA, and the inferior mesenteric artery (IMA). Symptoms are typically manifested when two of the three vessels are significantly stenosed or completely obstructed.

A review of the anatomy of arterial blood flow to the intestines is helpful in understanding the pathophysiology of mesenteric ischemia.

The celiac artery arises anteriorly from the abdominal aorta at the level of the 12th thoracic vertebra. The celiac artery branches into the common hepatic, splenic, and left gastric arteries. These vessels supply their corresponding organs with significant redundancies, so ischemia in these areas is rare.

The SMA comes off the aorta 1 cm below the celiac artery and terminates as the ileocolic artery. This latter vessel supplies the majority of the blood delivered to the small intestine, as well as some flow to the pancreas, right colon, and transverse colon.

The IMA originates from the aorta 7 cm distal to the SMA. It provides blood to the distal transverse colon, descending colon, and rectum.

There is a significant array of collateral blood vessels and flow patterns. The small intestine is especially vulnerable to ischemia, however, because the terminal arterioles enter the intestinal wall without collateral pathways.4 Splanchnic blood flow requirements vary continuously but can account for up to 35% of cardiac output.

Venous drainage of the system occurs via the superior mesenteric vein, which empties into the portal vein.

### Presenting Signs and Symptoms

#### Classic Presentation

Soon after ischemia begins, patients have complaints of severe abdominal pain that is clearly out of proportion to the findings on physical examination, such as a soft abdomen that is not very tender to palpation. The description and location of the pain vary over time. As the disease progresses, infarction develops and the symptoms may temporarily remit. Over the next several hours, bowel necrosis leads to signs of peritonitis: the abdomen becomes rigid, distended, and very painful with decreased bowel sounds. The intestinal mucosa begins to slough, and rectal bleeding occurs. At this point the stool contains occult blood in 60% of patients. The bowel may perforate, as signaled by findings of hypotension and sepsis.

Clues to diagnosis of the various ischemic bowel diseases are as follows:

- Acute abdominal pain followed by rapid and forceful evacuation of the bowels (vomiting or diarrhea) strongly suggests an embolic phenomenon in the SMA.
- Long-standing abdominal pain (weeks to months), which is then followed by acute worsening, suggests intestinal angina and SMA thrombosis.
- Patients with risk factors for NOMI may have unexplained abdominal distention or gastrointestinal bleeding; pain is totally absent in up to 25% of these patients, and unexplained distention may herald infarction.

Chronic mesenteric ischemia, or “intestinal angina,” refers to a pattern of pain typically brought on after eating that is usually episodic and recurrent, is sometimes constant, and lasts for up to 3 hours at a time. Mesenteric arterial atherosclerotic disease is generally the cause of chronic mesenteric ischemia, with a process similar to that of coronary artery disease and resultant angina pectoris.

Colonic ischemia occurs much less frequently than small bowel ischemia. Colonic ischemia often resolves spontaneously and without sequelae but can lead to significant morbidity and, in some cases, death.

#### Variations in Presentation

In patients with NOMI, the severity and location of pain vary, which complicates early diagnosis. A heightened level of suspicion is necessary for patients with significant risk factors.

Mesenteric vein thrombosis may be totally asymptomatic and might be diagnosed as an incidental finding in patients

undergoing CT of the abdomen for reasons other than abdominal pain. Blockage of the IMA may be silent because of adequate collateral circulation.

Patients with mesenteric atherosclerosis may have symptoms of abdominal angina, classically manifested as postprandial pain. As a result, fear of eating, early satiety, weight loss, and altered bowel habits develop. This syndrome occurs in up to 50% of patients in whom thrombotic mesenteric ischemia eventually develops.2

**DIFFERENTIAL DIAGNOSIS**

Few diagnoses portend a more serious course and risk for mortality than mesenteric ischemia does. Patients at risk for AMI are generally also at risk for aortic disease. Other items in the differential diagnosis are listed in Box 34.1.

**DIAGNOSTIC TESTING**

**ANGIOGRAPHY AND COMPUTED TOMOGRAPHIC ANGIOGRAPHY**

Mesenteric angiography provides direct visualization of the vasculature and remains a valuable method of evaluation in patients with suspected bowel ischemia (Table 34.3). Angiography is both sensitive (74% to 100%) and specific (100%); the test also differentiates between occlusive and nonocclusive disease. Patients who undergo angiography in timely fashion have better survival; mortality rates of 70% to 90% are observed when bowel infarction has occurred.4

CT angiography (CTA) is largely replacing standard angiography because it is more readily available and more quickly accomplished. A metaanalysis published in 2010 confirmed CTA as the first-line imaging modality because of its high sensitivity (93%) and specificity (96%).5 CTA is clearly more advantageous in the ED; interventional radiology (IR) involvement later offers additional treatment advantages in the perioperative or observational inpatient phases.

**BOX 34.1 Differential Diagnosis of Ischemic Bowel Disease**

- Abdominal aortic aneurysm: rupture or expansion
- Perforated ulcer or viscus
- Ruptured ectopic pregnancy (woman of childbearing age)
- Incarcerated or strangulated hernia
- Septic shock
- Intussusception
- Volvulus
- Salpingitis or tuboovarian abscess
- Torsion of the ovary or testicle
- Appendicitis
- Pelvic mass or torsion
- Pancreatitis
- Diverticulitis
- Ruptured ovarian cyst
- Renal colic
- Biliary colic

Also consider atypical manifestations of:
- Inferior wall myocardial infarction
- Pulmonary embolism
- Pneumonia
- Diabetic ketoacidosis
- Acute glaucoma

*Different diagnoses are listed in order of urgency.

**DOCUMENTATION**

- Onset, severity, and duration of symptoms
- Presence of melena or hematochezia
- Presence or absence of risk factors
- Vital signs: evidence of shock, sepsis
- Findings of cardiac, full abdominal, genitourinary, and rectal examinations
- Emergency department course: times of discussions with consultants, discussions with family, code status, availability of testing, treatments, delays
Standard angiography allows local administration of thrombolytic or vasodilatory therapy concomitant with the diagnostic procedure, thereby improving mortality. The emergency physician (EP) must weigh the diagnostic and therapeutic advantages of CTA or standard angiography against concerns for dye administration in patients susceptible to renal insufficiency (almost every patient with mesenteric ischemia), availability of an interventional radiologist, stability of the patient, and delays in surgical intervention (Fig. 34.1). In all cases of suspected mesenteric ischemia, the surgeon should be contacted for involvement before or simultaneously with the ordering of advanced diagnostic testing, with the caveat that any delay in diagnosis and operative intervention increases mortality.

With the exception of contrast-enhanced CT scans for mesenteric vein thrombosis, all other imaging tests are fraught with error and lead to diagnostic delays. Standard CT should not be considered an alternative to CTA or standard angiography for the definitive diagnosis of mesenteric ischemia. Once the diagnosis is considered seriously, all testing and consultation should be arranged in parallel rather than sequentially.

**COMPUTED TOMOGRAPHY**

Early CT findings of acute arterial ischemia are poorly sensitive and nonspecific; late findings identify disease in patients with prolonged ischemia and probable necrosis (Table 34.4). CT is the imaging test of choice only for mesenteric vein thrombosis, for which it has a diagnostic accuracy of 90%.6 Angiography may be avoided when the diagnosis of SMV thrombosis is confirmed by standard CT, although it may still be used for catheter placement and local papaverine infusion.

**OTHER IMAGING MODALITIES**

Magnetic resonance angiography (MRA) with gadolinium enhancement is useful for evaluation of the proximal celiac trunk and SMA. MRA less accurately identifies disease of the IMA, peripheral vessel disease, and NOMI. The findings are similar to those with CT. In the future, rapid MRA may replace angiography for the diagnosis of ischemic bowel disease.

Duplex ultrasonography can assess flow and thrombosis in the SMA or the portal vein. Ultrasonography is frequently limited by the patient’s symptoms, condition, and abdominal distention. It is accurate only for evaluation of proximal vessel disease; false-negative results are common in cases of NOMI or distal disease.

Plain radiographs have no role in the evaluation of acute ischemic disease but are frequently ordered to quickly assess for the presence of processes such as a perforated viscus and free air. Plain film findings are usually normal early in the course of illness. Late findings suggest mucosal edema and hemorrhage and include bowel wall thickening, ileus, and thumbprinting, which describes the appearance of bowel wall edema, as though a thumb had been pressed into the bowel wall and caused an indentation. Pneumatosis intestinalis, the presence of gas in the bowel wall, may also be seen. Air in the portal venous system may likewise be seen (Fig. 34.2). Late findings are associated with a poor prognosis.

**LABORATORY STUDIES**

No laboratory studies are confirmatory of mesenteric ischemia. Delaying diagnostic imaging by waiting for laboratory results decreases survival. Laboratory abnormalities are nonspecific and occur late in disease (Box 34.2)4,7,9; their absence in no way rules out acute ischemia.5,9

An elevated serum amylase level is commonly noted with bowel infarction and sometimes leads to an incorrect diagnosis of pancreatitis. The EP should beware of the presence of elevated amylase when the serum lipase value is normal. Diffuse elevation of liver enzymes is seen with hepatic involvement and ischemia.

Levels of ischemia-modified albumin increase in AMI, as well as in several other vascular diseases; their potential role in early diagnosis remains undefined.10

</table>

Early surgical consultation is a high priority in patients with suspected mesenteric ischemia. Initial ED management should include volume resuscitation, treatment of contributing cardiac abnormalities (dysrhythmias, heart failure, hypotension), and administration of broad-spectrum antibiotics (Box 34.3). Administration of antibiotics decreases the infectious complications of bowel infarction when they are given early to patients with suspected ischemia. The most difficult process for the EP is to see past the present crisis and perform a complete and thorough evaluation of the patient; atrial fibrillation with a rapid ventricular response is a common finding, but hypotension and the altered mental status attributed to it may actually be due to the resultant mesenteric ischemia and sepsis. Look for and pay attention to the other findings pointing to coexisting diagnosis.

Blood tests and radiographs might be ordered to exclude other causes during the wait for surgical consultation and angiography. Placement of a nasogastric tube reduces abdominal distention and may improve the symptoms; nothing should be given by mouth. Blood typing and cross-matching should be performed in the expectation that the patient will undergo surgery. Central venous pressure monitoring may be useful to ensure adequate volume resuscitation in critically ill patients.

Surgical exploration is mandatory when peritonitis is present to remove necrotic bowel and restore blood flow via arterial bypass or embolectomy. A second-look procedure is generally performed 12 to 24 hours after the first operation to evaluate for additional loss of bowel (Fig. 34.3).

When peritonitis and gastrointestinal bleeding are not present, thrombolytic agents or vasodilators (papaverine), or both, are useful measures that may avoid surgery. Thrombolytics given within 12 hours of the onset of symptoms may completely resolve a partially obstructing or distal thrombus. Vasospasm may become irreversible if not addressed early; it can lead to bowel necrosis even after surgical embolectomy or thrombolyis. Papaverine is infused locally at 30 to 60 mg/hr for vasodilation via an IR-placed angiography catheter for all causes of ischemic bowel disease. Papaverine is routinely and safely administered from the preoperative period to several days after surgery. Vasodilation may be used as monotherapy in patients with minor emboli or those who have major emboli but for whom surgery poses a high risk. Reperfusion of vascular structures distal to the obstruction must be demonstrated by angiography.

Placement of intravascular stents is successful in selected cases of SMA thrombosis. Mesenteric vein thrombectomy is similarly useful in certain cases of mesenteric vein thrombosis. Anticoagulation is routinely administered postoperatively to patients with mesenteric vein thrombosis. Immediate heparinization after surgery decreases the chance of thrombus recurrence from 25% to 13%, prevents disease progression, and reduces mortality from 50% to 13%. With the absence of peritonitis, anticoagulation may be used in lieu of surgery. If deemed successful after close observation, anticoagulation therapy is generally continued for 3 to 6 months.

**Figure 34.2** Pneumatosis intestinalis. A computed tomography scan shows intramural gas (arrow) in the bowel wall caused by bowel infarction from a superior mesenteric artery embolus. (From Hendrickson M, Narpass TR. Abdominal surgical emergencies in the elderly. Emerg Med Clin North Am 2003;21:937-69.)

**BOX 34.2 Laboratory Abnormalities in Late-Stage Mesenteric Ischemia**

- Leukocytosis (white blood cell count > 15,000 cells/mm³)
- Metabolic acidemia
- Elevated serum lactate
- Elevated d-dimer
- Elevated serum and peritoneal amylase (with normal lipase)
- Bacteremia

**TIPS AND TRICKS**

- Suspect the disease, especially in the elderly.
- Do not delay obtaining imaging or consultation while waiting for laboratory test results.
- Rectal findings are often normal.
- An elevated serum amylase value may suggest bowel infarction, not pancreatitis.
- A patient with a history of deep vein thrombosis is at risk for superior mesenteric vein thrombosis, which tends to develop less acutely than other causes of ischemia.
- Bowel ischemia promotes acidosis, lethargy, and confusion in the elderly; altered mental status complicates up to 30% of cases.

**BOX 34.3 Emergency Department Treatment**

- Fluid resuscitation and oxygen supplementation; treat shock as indicated
- Apply telemetry monitoring and obtain an electrocardiogram
- Broad-spectrum antibiotics to cover bowel flora
- Nasogastric tube and Foley catheter
- Address comorbid conditions with specific treatment
- Surgery consultation as soon as the diagnosis is strongly suspected

**TREATMENT**
Additional therapeutic possibilities currently being explored include the use of heparin-binding epithelial growth factor–like growth factor to protect the intestines and other organs from ischemic injury, percutaneous transluminal angioplasty of the SMA, tolazoline and nitroglycerin as local intraarterial infusions, and prostaglandin E1 infusions in patients with NOMI.12-16

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Critical care admission is required for all patients with ischemic bowel disease regardless of whether they are to undergo surgical or medical management.

**PATIENT TEACHING TIPS**

Have an early discussion with the patient and family regarding the severity of the illness, need for an aggressive approach to diagnosis and treatment, and high mortality.

Determine the patient’s and the family’s desire for full resuscitation efforts given the mortality rate associated with mesenteric ischemia.

Diverticulitis

Kelly P. O’Keefe and Tracy G. Sanson

**KEY POINTS**

- Diverticulitis is an acute inflammatory process caused by injury and bacterial proliferation in an existing diverticulum.
- Patients with diverticular disease may be seen in the emergency department with inflammation manifested as abdominal pain or, less commonly, with hematochezia.
- Consider complicated disease (perforation of a diverticulum or abscess formation) and surgical consultation in patients who have peritoneal findings on examination.

**PATHOPHYSIOLOGY**

**DIVERTICULOSIS**

Diverticula are thought to arise from defects in the muscularis layer of the intestines (Fig. 35.1) and are related to abnormalities in muscle tone and increased intraluminal pressure; saclike protrusions eventually form at points of weakness. If stool is caught in these sacs, it becomes inspissated and hardened and causes abrasions of the mucosa that lead to inflammation, although the same end result can occur from pressure differentials alone without the presence of trapped fecal material.

Diverticula generally form at a site of focal weakness in the wall of the bowel, such as the location of blood vessel penetration (vasa recta). The mucosal and submucosal layers herniate through the muscular layer of the intestine, with only a covering of serosa remaining. This leads to an inherent weakness in the diverticular sac relative to the normal bowel. Only thinned layers of mucosa protect blood vessels, which are subject to stretching and thinning of their media, thereby predisposing to weakness and rupture of the vascular tissue.

The left side of the colon is the most common site for diverticulosis in patients with westernized diets and lifestyle. Right-sided diverticula occur more frequently in certain Asian populations. Right-sided diverticula have a higher rate of hemorrhage because of anatomic differences in their development. Small bowel diverticula occur most commonly in the duodenum, where they are predominantly asymptomatic. About 20% of small bowel diverticula occur in the jejunum or ileum; complications develop in these diverticula at rates three times greater than in duodenal diverticula.

A low-fiber diet and constipation may contribute to the development of diverticular disease. High-fiber diets that prevent constipation clearly lead to fewer relapses of diverticulitis and less frequent complications. Lack of physical activity and advanced age are both believed to increase the incidence of the disease. Men and women are affected equally.

**DIVERTICULITIS**

Diverticulitis arises from the initial microperforation of a diverticulum (Table 35.1). The process starts with blockage of the colonic opening of the diverticulum or by direct contact with food and fecal particles lodged in the affected portion of the bowel. Increased intraluminal or direct local pressure causes erosion of the diverticular wall, which leads to inflammatory changes, focal necrosis, and eventually perforation. The process is generally mild and limited by local pericolic fat and mesentery. Virtually all cases of diverticulitis involve perforation of the intestines, with the course of the resultant...

illness determined by the extent of this perforation. Complicated diverticulitis refers to regional spread of the inflammatory process by the formation of larger abscesses, a fistula with adjacent organs, or peritonitis (Fig. 35.2). Patients with purulent peritonitis have a mortality rate of 6%, which rises to 35% when fecal soilage of the peritoneal cavity occurs. Patients with diverticular disease occasionally have segmental colitis of the sigmoid colon, probably from fecal stasis or localized ischemia. The effects can be mild or may resemble those of inflammatory bowel disease.

PRESENTING SIGNS AND SYMPTOMS

HISTORY AND PHYSICAL EXAMINATION

A focused history and physical examination are important in making the diagnosis of diverticular disease. Essential historical elements are bowel habits, diet, elucidation of classic symptoms, and previous occurrence. Physical examination should assess for hemodynamic stability, the presence of peritonitis, and occult or obvious hemorrhage. Complete abdominal, genitourinary, and rectal examinations must be documented.
The classic manifestation of diverticulitis involves several days of worsening left lower quadrant abdominal pain. Low-grade fever commonly develops but is not uniformly present. Patients typically report similar past episodes of pain and fever. Other common symptoms are nausea, vomiting, constipation (50%), and diarrhea (40%). Urinary symptoms (dysuria, urgency, frequency) caused by local inflammation of the bladder occur in only 10% of patients. Fever is often absent in elderly patients, and a rectal temperature may be required for detection of fever in this population. Dementia, polypharmacy, and other causes of chronically altered mental status may complicate diagnostic accuracy; imaging should be used liberally in these patients. Signs of peritonitis may be minimal or absent in even the most fully competent and communicative older patient.

**RED FLAGS**

- Hospitalize patients with signs and symptoms of systemic illness, even without clear peritonitis.
- Consider risk factors for abdominal aortic aneurysm and mesenteric ischemia.
- Rectal findings can be negative or normal in a patient with episodic diverticular bleeding.

**DIFFERENTIAL DIAGNOSIS**

Box 35.1 presents the differential diagnosis for suspicion of diverticulitis.

**LABORATORY TESTS**

Leukocytosis is noted in only half of patients with diverticulitis. Disease severity, advancing age, and underlying health status affect the white blood cell count; it may not be elevated in elderly patients or the chronically ill even with significant acute disease. Similarly, hemoglobin levels may not accurately reflect the severity of recent diverticular bleeding. Urinalysis should be performed to evaluate any urinary symptoms; abnormalities may reflect inflammatory changes, infection, or contamination via colovesicular fistula formation. Blood cultures should be obtained with any suspicion of sepsis.

Additional laboratory testing is helpful in excluding other processes. Standard tests for the evaluation of abdominal pain should be ordered when indicated, including a complete blood count, metabolic panel, liver function tests, and lipase. An elevated serum lipase value should reliably diagnose acute pancreatitis. Typing and crossmatching of blood should be performed in patients with hematochezia or signs of a surgical abdomen. Coagulation tests are indicated for bleeding patients, for those taking anticoagulant medications, and for critically ill patients at risk for disseminated intravascular coagulopathy. A pregnancy test is required for any woman of childbearing age who complains of abdominal pain.

**IMAGING**

Plain radiographs of the chest and abdomen are useful to evaluate for the presence of other processes but do not assist in the diagnosis of diverticular disease. Free air is occasionally present in patients with a perforated diverticulum. Evidence of ileus or obstruction may be seen with complicated disease.

Computed tomography (CT) of the abdomen and pelvis is the test of choice for confirming the diagnosis of diverticulitis, assessing its severity and complications, and directing intervention. CT findings for and complications of diverticular disease are listed in Box 35.2.

Contrast enema studies are less expensive than CT and are better able to evaluate the lumen of the colon. They are generally performed with water-soluble agents rather than barium given the high likelihood of perforation in patients with
diverticulitis. Contrast enema studies provide little information, however, about complications of diverticular disease.

Compression ultrasonography is a relatively new diagnostic procedure for diverticular disease. Ultrasonography may be used to serially assess fluid collections or to assist in the transrectal or transvaginal drainage of abscesses. The “pseudokidney” sign (thickening of the bowel wall that mimics the appearance of a kidney) may represent acute diverticulitis and aid in rapid diagnosis by ultrasound. This finding, however, is not specific to diverticular disease.6

Colonoscopy and flexible sigmoidoscopy have limited roles in evaluating diverticulitis in the acute setting. All patients with diverticulitis should be referred for outpatient colonoscopy when their acute illness has subsided. These modalities allow direct visualization of the colonic lumen and biopsy of any lesions. Colonoscopy remains an important initial diagnostic procedure for patients with acute diverticular bleeding.

**TREATMENT**

The majority of patients with acute, uncomplicated diverticulitis respond to bowel rest and antibiotics (Box 35.3).6 The remaining patients require various levels of intervention ranging from percutaneous drainage of abscesses to laparoscopic or other surgical procedures. The surgical mortality rate ranges from 1% to 5%, depending on comorbid conditions and the severity of disease.

Fluid resuscitation is needed in patients with dehydration, peritonitis, complicated disease, and significant bleeding. Patients with evidence of peritonitis or other disease complications require surgical consultation and admission. Patients with complicated disease should take nothing by mouth. Nasogastric decompression should be used in patients with symptomatic ileus.

Pain medication is necessary in most patients with acute diverticulitis. Narcotic analgesics may slow recovery because they promote constipation; patients should be warned to limit the use of these medicines or use adjunctive bulk laxatives. Patients with significant pain should be admitted to the hospital. Titration of pain medication should begin in the ED as indicated by the patient’s reported pain scale, not based on the timing of examination by the consultant surgeon. Fentanyl is easily titrated in parenteral doses of 25 to 50 mcg, is short acting, and causes minimal histamine release or hemodynamic instability.

**CONSULTATION**

Surgical consultation should be obtained immediately for patients with peritonitis or a vascular catastrophe. Consultants should be notified early in the treatment of elderly or immunocompromised patients, as well as for patients with clear indications of complicated disease. Twenty-five percent of patients with a new diagnosis of diverticulitis have complicated disease and require surgical intervention. Patients with uncomplicated disease may require only follow-up with a surgeon on an outpatient basis. One third of these patients eventually require surgery.6

**PRIORITY ACTIONS**

Establish intravenous access for the management of diverticulitis.

Obtain a pertinent history and perform a physical examination, including rectal and genitourinary examination.

Consider life-threatening conditions in the differential diagnosis.

Obtain surgical consultation for any patients with evidence of peritonitis.

Arrange for radiographic and laboratory analysis.

---

**BOX 35.2 Computed Tomography in Diverticulitis**

**CT Features of Acute Diverticulitis**

- Increased soft tissue density with pericolic fat changes (98%)
- Colonic diverticula (84%)
- Bowel wall thickening (70%)
- Soft tissue fluid collections or abscess (35%)

**Complications of Diverticulitis Found on CT**

- Peritonitis (diffuse inflammatory changes, scattered loculated fluid collections)
- Fistula formation
- Bowel obstruction
- Diverticular disease is indistinguishable from carcinoma of the colon in up to 10% of patients

**BOX 35.3 Treatment: Antibiotics for Diverticulitis**

Antibiotic therapy should be directed against the usual colonic flora, particularly gram-negative rods and anaerobes (especially *Escherichia coli* and *Bacteroides fragilis*). Suitable regimens are as follows:

- Piperacillin-tazobactam
- Ticarcillin-clavulanate
- Ampicillin, gentamicin, and metronidazole
- Imipenem-cilastin or other carbapenems
- Ampicillin-sulbactam (outpatient)
- Quinolone and metronidazole (outpatient)
- Sulfamethoxazole-trimetoprim and metronidazole (outpatient)
- Cefazolin and metronidazole (outpatient)*
- Ceftriaxone and metronidazole

*Clindamycin is an acceptable alternative to metronidazole for the coverage of anaerobes.
Intestinal obstruction is a rare complication of diverticular disease and generally arises from the small bowel rather than the large bowel. Obstructions result from chronically diseased bowel and adhesion formation. Recurrent attacks of acute disease can cause strictures and narrowing of the lumen of the colon as well, but subsequent complete obstruction of the large bowel is uncommon.

Overall complications from diverticulosis of the small bowel are unusual when compared with those from disease of the colon. Rarely reported problems include massive gastrointestinal hemorrhage from an arteriovenous malformation located in the submucosa of a jejunal diverticulum, a diverticulum-induced ileoabdominal fistula, and cases of small bowel obstruction with volvulus.\textsuperscript{4,7-9}

Duodenal diverticula have been associated with a higher rate of common bile duct stones identified on endoscopic retrograde cholangiopancreatography.\textsuperscript{10,11} This finding may be due to higher rates of bacterial contamination in the biliary system in patients with small bowel diverticula.\textsuperscript{15} Rarely, congenital intraluminal diverticula may lead to recurrent abdominal pain and obstructive symptoms.

Jejunocolic diverticula occur in 1% of the population and may cause malabsorption from chronic bacterial overgrowth. Other symptoms include early satiety, bloating, and chronic upper abdominal discomfort.

Colonic diverticular bleeding is generally manifested as painless hematochezia that is self-limited. The amount can be voluminous, with the blood being maroon or bright red. Because bleeding commonly occurs without other signs of inflammation, the abdominal findings may be unremarkable. Only 5% of patients with diverticular bleeding have massive, hemodynamically significant gastrointestinal hemorrhage. These patients are typically older than 60 years and have comorbid conditions.

Ninety percent of all diverticular fistulas arise from the sigmoid portion of the colon. Classically involved organs are the bladder, vagina, skin, and noncontiguous bowel. Colovesiculic fistulas occur more commonly in men than in women because of interposition of the uterus between the colon and bladder; fistulas involving the ureter or fallopian tubes are unusual. Enterovesical fistulas may lead to gas in the mesenteric and hepatic portal veins, and septic thrombophlebitis (pylephlebitis) may occur as well.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with uncomplicated diverticulitis can be considered for discharge on the basis of hydration status, ability to tolerate oral fluids, pain level, comorbid conditions, immune function, home support, age, reliability of follow-up, and ability to obtain antibiotics and take them as required. Those with high fevers and significant leukocytosis should be admitted because of the potential for bacteremia or undetected complications. Patients with complex underlying medical diseases should undergo a period of inpatient observation if there is any concern that the disease may progress to perforation or sepsis.

Inflammatory Bowel Disease
James Ahn

**PATHOPHYSIOLOGY**

**CROHN DISEASE**

*Pathology*
Crohn disease is characterized by segmental, transmural, granulomatous inflammatory changes that can occur anywhere along the gastrointestinal tract from the mouth to the perianal area. Disease of the terminal ileum is present in 80% of patients with Crohn disease, and 50% of patients have ileocolitis. Approximately 33% and 20% of patients demonstrate only ileal and colonic involvement, respectively. The finding of skip lesions between areas of normal bowel and cobblestoning of the intestinal mucosa is classic for Crohn disease. Chronic inflammation commonly leads to bowel stenosis.

*Epidemiology*
The yearly incidence of Crohn disease is between 3 and 14 cases per 100,000 people in North America, with a disease prevalence of 26 to 201 cases per 100,000. The incidence rate of Crohn disease has risen steadily, with the highest incidence found in North America and Northern Europe. Crohn disease is more common in Caucasian and Latino people in the United States than in African Americans, Native Americans, and Asian Americans. Women have a 20% to 30% higher incidence than men do.

The cold chain hypothesis suggests that the rise in incidence of Crohn disease has been associated with the development of home refrigeration techniques. Bacteria that thrive in refrigerated foods, such as *Yersinia* and *Listeria*, are thought to play a role in stimulation of the immune and inflammatory responses that ultimately lead to Crohn disease. Exacerbations of Crohn disease may be worsened during periods of higher physiologic or mental stress. Other environmental factors such as cigarette smoking, use of nonsteroidal antiinflammatory drugs (NSAIDs), increased refined sugar intake, increased dietary fat, and decreased fiber intake have been linked to the development of Crohn disease.

Genetic mutations and chromosomal variants have also been linked to the development of Crohn disease. Specific alterations in the *NOD2* gene are associated with a 20-fold increase in the likelihood of Crohn disease with ileal predilection. Patients with Crohn disease may also be HLA-B27 positive.

**KEY POINTS**

- Acute exacerbations of inflammatory bowel disease are characterized by abdominal pain, nausea, vomiting, diarrhea, and gastrointestinal bleeding.
- Life-threatening complications include bowel obstruction, hemorrhagic shock, toxic megacolon, malabsorption, abscess formation, and sepsis.
- Treatment with analgesics, intravenous hydration, antiemetics, and electrolyte replacement should occur in parallel with appropriate diagnostic imaging and laboratory studies.
- Antibiotics, steroids, and immunosuppressant therapies can be used in conjunction with specialty consultation.
- Hypersensitivity reactions may result from long-term immunomodulator and antiinflammatory therapies.
- Patients receiving immunosuppressant therapy have increased susceptibility to opportunistic infections.

**PERSPECTIVE**

Approximately 1 million people in the United States suffer from inflammatory bowel disease (IBD). The two major forms of IBD are Crohn disease and ulcerative colitis (UC). The incidence of both disease processes is similar, although Crohn disease appears to be increasing. Each disease may relapse and remit, with exacerbations that often require emergency care and hospitalization.

IBD has a familial predilection, with an absolute risk of 7% among first-degree relatives. Up to a fifth of patients with IBD have an affected first-degree family member. Ashkenazi Jewish populations continue to have the highest documented incidence per capita of any group in the world. Hispanic and African American populations have a lower incidence of IBD than the Caucasian population does.

The age at onset of IBD is bimodal. The greatest numbers of new cases are diagnosed in patients 15 to 35 years of age. Classically, a second peak is observed during the sixth decade of life. Advances in diagnostic testing have probably contributed to an overall rise in the number of new cases of IBD, as well as to the identification of the disease in younger patients.
CHAPTER 36  
INFLAMMATORY BOWEL DISEASE

Clinical Presentation
Patients with Crohn disease typically have abdominal pain, fever, diarrhea, and weight loss. Because Crohn disease involves the entire gastrointestinal tract, patients may suffer from oral ulcers, odynophagia, dysphagia, and symptoms of gastric outlet obstruction. Sinus tracts may develop and lead to common complications such as abscesses and fistula formation. Patients with Crohn disease can also have gastrointestinal bleeding, though to a lesser extent than patients with UC. Other complications include bowel obstruction, fissures, malignancy, malabsorption, malnutrition, and hypocalcemia.

Crohn disease is associated with an increased risk for demyelinating diseases, as well as a higher incidence of inflammatory processes such as asthma, arthritis, bronchitis, psoriasis, and pericarditis. Approximately 20% of patients with Crohn disease experience one or more of the following extraintestinal manifestations of disease during their lifetimes: ankylosing spondylitis, uveitis, episcleritis, hepatitis, cholelithiasis, pancreatitis, primary sclerosing cholangitis, cholangiocarcinoma, nephrolithiasis, and erythema nodosum (Fig. 36.1; Box 36.1).

ULCERATIVE COLITIS
Pathology
UC is a recurring inflammatory disease confined to the mucosal layer of the colon and rectum only. Areas of inflammation are continuous, not segmental; patients commonly experience ascending disease from the rectum to the colon. Isolated rectal involvement is present in a minority of patients.

Epidemiology
The yearly incidence of UC is relatively constant—in the United States it is 8 per 100,000 people, with a disease prevalence of 246 cases per 100,000 people. The etiology of this disease is unknown, although certain risk factors have been identified. UC is most commonly found in North American and Northern European Caucasian populations. In addition, similar to Crohn disease, development of UC has been linked to the use of NSAIDs, increased refined sugar intake, increased dietary fat, and decreased fiber intake. However, cigarette smoking appears to lessen the risk for development of UC.

Clinical Presentation
Although UC has variable findings, bloody, purulent, and mucoid diarrhea is considered to be the classic manifestation. Fever, weight loss, dehydration, anemia, and hypoalbuminemia are common. Patients may be categorized as having mild disease (60%), moderate disease (25%), or severe disease (15%). Severe disease is defined as six or more bowel movements per day.

Significant lower gastrointestinal bleeding is the most common complication, with 3% of patients with UC having massive hemorrhage. Patients may also have toxic megacolon as a complication of fulminant colitis. Toxic megacolon causes a loss of colonic muscular tone that results in luminal diameters larger than 6 cm—pathologic changes that increase the risk for perforation and mortality. Long-term complications of UC include bowel strictures and the development of colon cancer.

Patients with UC may have extraintestinal complications such as concurrent arthritis, uveitis, erythema nodosum, pyoderma gangrenosum, and progressive liver disease (Fig. 36.2; Table 36.1).

DIAGNOSTIC TESTING
IMAGING MODALITIES
Most cases of IBD diagnosed in the emergency department (ED) are found via computed tomography (CT) of the abdomen in patients with severe, unexplained abdominal pain. A presumptive diagnosis of IBD can be based on typical CT findings coupled with the appropriate signs and symptoms. CT enterography has been shown to have 100% sensitivity and 95% specificity for detection of small bowel lesions associated with Crohn disease. CT enterography is superior to

BOX 36.1 Differential Diagnosis: Colitis

Inflammatory bowel disease:
- Crohn disease

standard CT of the abdomen and pelvis in patients with a high pretest probability of Crohn disease (i.e., first-degree family members of patients with IBD). Confirmation of the diagnosis is made by histologic examination of tissue biopsy specimens obtained via inpatient endoscopy or surgery.

Patients seen in the ED with an exacerbation of known IBD do not always require CT. Plain films are generally sufficient to exclude complications such as bowel obstruction and rare perforations. CT should be used to identify abscesses or other intraabdominal disease in patients with peritoneal findings or sepsis.

Other imaging modalities are best used outside the ED. Barium and air-contrast radiographic studies frequently demonstrate classic radiographic evidence of IBD; they are useful tests for obese patients who exceed the weight limit for standard CT scanners. Upper and lower endoscopy allows direct visualization and biopsy of suspected lesions. Technology that enables patients to swallow endoscopic cameras as capsules represents a promising, minimally invasive method to visualize the bowel mucosa.

LABORATORY TESTS

Laboratory studies have limited value in the ED evaluation of IBD. Most tests serve to exclude complications or alternative diagnoses. A complete blood count can provide a baseline hemoglobin level. Leukocytosis is a nonspecific finding in patients with chronic IBD; marked elevations in the white blood cell count may correlate with new abscess formation, toxic megacolon, sepsis, or corticosteroid therapy. A serum chemistry panel is needed to exclude hypokalemia, hypocalcemia, and electrolyte imbalances in patients with severe vomiting and diarrhea. Hypoalbuminemia is often detected with liver function tests. The erythrocyte sedimentation rate and C-reactive protein levels add little value for guiding ED therapy.

Serologic markers may be used to differentiate Crohn disease from UC. The presence of p-ANCAcs (perinuclease-staining antineutrophil cytoplasmic antibodies) is sensitive and predictive of UC, whereas detection of ASCA (anti—Saccharomyces cerevisiae antibodies) markers probably predicts Crohn disease. These serologic tests are not indicated for use in the ED.

TREATMENT

GENERAL MANAGEMENT

Exacerbations of IBD are often marked by significant pain, fever, diarrhea, gastrointestinal bleeding, anorexia, and dehydration; severity is most pronounced in patients with chronic disease who seek treatment in the ED because of exacerbations. Management of symptoms should be done in parallel with diagnostic testing. Analgesics, antiemetics, and intravenous hydration should be administered on arrival of the
Inflammatory Bowel Disease

Treatment algorithm for Crohn disease.

- Treatment algorithm for ulcerative colitis.

- Common medications

Sulfasalazine is a first-line oral agent used for the treatment of mild to moderate IBD. Colonic bacteria cleave the drug into 5-aminosalicylic acid (5-ASA) and sulfapyridine. 5-ASA acts directly on intraluminal lesions without systemic absorption. Although its mechanism of action is still unclear, 5-ASA probably inhibits leukocyte chemotaxis, as well as prostaglandin and leukotriene production. Sulfapyridine is a toxic by-product responsible for a variety of dose-related adverse effects (nausea, vomiting, diarrhea, headache, abdominal pain, arthralgias) and hypersensitivity reactions (rash, bone marrow suppression, fever, pancreatitis, liver disease, nephrotoxicity). Sulfasalazine at doses of 4 g or more per day should produce a clinical response within 3 to 4 weeks. Oral, enema, and suppository preparations of sulfasalazine are available.

Oral steroids improve mild to moderate IBD symptoms within days to weeks and are used in patients who do not improve with 5-ASA agents. Prednisone, 40 mg/day, is an acceptable starting dose; equivalent parenteral administration should be reserved for severe disease or for patients who cannot tolerate oral medications. Long-term corticosteroid therapy at a low maintenance dose is often required. Patients with small bowel obstruction secondary to terminal ileitis may have a response to early treatment with steroids, thereby reducing the need for surgical intervention (Fig. 36.5).

Patients with Crohn disease can benefit from maintenance therapy with azathioprine or its active metabolite 6-mercaptopurine (6-MP). These immunomodulator drugs inhibit lymphocyte proliferation and subsequent activation of the inflammatory cascades. Their onset of action is 3 to 5 months in most cases. 6-MP is reserved for patients with disease refractory to other medications. Adverse effects include pancreatitis, leukopenia, hepatitis, and lymphoma. Methotrexate is another immunosuppressant that is used for Crohn disease refractory to 6-MP or in patients exhibiting Crohn disease–related arthritis. Adverse effects of methotrexate include leukopenia, anemia, thrombocytopenia, hepatobiliary complications, pericarditis, and thrombosis.

### Treatment Algorithm for Crohn Disease

![Fig. 36.3](image1)

**Fig. 36.3** Treatment algorithm for Crohn disease. 5-ASA, 5-Aminosalicylic acid; IV, intravenous; TPN, total parenteral nutrition. (From Goldman L, Ausiello D, editors. Cecil’s textbook of medicine. 22nd ed. Philadelphia: Saunders; 2003.)

### Treatment Algorithm for Ulcerative Colitis

![Fig. 36.4](image2)

**Fig. 36.4** Treatment algorithm for ulcerative colitis. 5-ASA, 5-Aminosalicylic acid. (From Goldman L, Ausiello D, editors. Cecil’s textbook of medicine. 22nd ed. Philadelphia: Saunders; 2003.)

Patient. In the setting of refractory emesis or bowel obstruction, nasogastric tube decompression may provide substantial relief. Identification and treatment of electrolyte imbalances, concurrent infections, and hemorrhage should precede hospital admission.

Immunomodulator, antiinflammatory, and antibiotic agents should be given in consultation with the patient’s gastroenterologist. Because these medications often require long-term administration and dose adjustments, complex drug regimens are typical. Treatment algorithms for Crohn disease and UC are summarized in Figures 36.3 and 36.4.
SECTION IV  GASTROINTESTINAL DISEASES

Fig. 36.5 Plain radiograph showing small bowel obstruction as a result of terminal ileitis.

Infliximab (Remicade) is an inhibitor of tumor necrosis factor that is administered intravenously for the control of severe, refractory Crohn disease. Complications of infliximab therapy are sepsis, hepatotoxicity, pneumonia, lupuslike syndrome, hypersensitivity reactions, lymphoma, leukopenia, and demyelinating disease. Infliximab, as well as cyclosporine, may be beneficial in the treatment of patients awaiting surgical intervention. Because of the strong immunosuppressant nature of certain IBD therapies, a high index suspicion for opportunistic infections must be maintained.

Antibiotics may be needed to treat patients with Crohn disease. Antibiotics are indicated for active Crohn disease and pouchitis; promising results have been shown for fistulizing Crohn disease.\textsuperscript{22-25} The antibiotics most commonly used are a combination of metronidazole and ciprofloxacin. The utility of these agents for UC has not been proved.

SURGERY
Seventy-five percent of patients with Crohn disease require surgery within the first 20 years after diagnosis. Emergency consultation should be obtained for patients with complications of IBD-related surgery or for patients with suspected life-threatening complications, including massive hemorrhage, abscess formation, obstruction, toxic megacolon, and perforation. Intravenous hydration, nasogastric decompression, and broad-spectrum antibiotic therapy should be given in preparation for surgery.

DISPOSITION
Hospital admission is required for moderate to severe exacerbations of IBD. Patients with severe dehydration, systemic infection, abscesses, or potentially life-threatening complications such as hemorrhage, toxic megacolon, perforation, and bowel obstruction must be managed as inpatients. Discharge should be reserved for patients with mild disease in whom oral hydration and pain control are easily attained. Changes in medication and disposition should be decided in consultation with a gastroenterologist.

REFERENCES

nursing home residents are taking laxatives daily. The condition is much less common in populations with non-Western diets containing more bulk. Although many people do not seek medical attention for their constipation, this condition is estimated to result in almost $7 billion in medical costs in the United States each year.

PATHOPHYSIOLOGY

Constipation is often multifactorial, with disordered movement of stool through the colon and anorectum. Oral intake, hydration, and general mobility affect colonic function. Numerous anatomic and structural entities, gastrointestinal (GI) disorders, medications, and systemic disorders may secondarily lead to constipation (Boxes 37.1 to 37.4) by altering intraluminal contents, fluid balance, intestinal contractions, or neuromuscular coordination. However, the majority of patients have primary chronic functional constipation that falls into one or more of three categories. Many actually have normal intestinal transit time; their constipation is perceptual and related to habits. Others have slow transit times because of overall colonic slowing (pancolonic inertia) or sigmoid spasm (left colonic hypermotility with uncoordinated segmental contractions and poor propulsion). An important but under-recognized group has pelvic floor dyssynergy (obstructive defecation), an acquired behavioral condition that begins with chronically ignoring the urge to defecate. Disordered defecatory function of the pelvic floor muscles and sphincters eventually produces difficulty expelling stool, even if soft. Hormonal contributions are unclear, but constipation is common in pregnancy and before menstruation. Contrary to past thinking, chronic laxative abuse does not cause chronic constipation. High rates in the elderly are not due to aging itself but to concomitant conditions or medications.

PRESENTING SIGNS AND SYMPTOMS

To the physician, the term constipation usually means a reduced frequency of bowel movements (less than three per week in Western culture) or difficult passage of hard stool (or both). To the patient, constipation may mean frequency reduced to less than daily, decreased volume per defecation, passage of hard stool, difficulty passing stool, straining, a feeling of incomplete evacuation, abdominal pain, rectal pain,
inability to defecate when desired or without a laxative, abdominal distention or bloating, or any combination thereof. An individual’s perception of what is “normal” is also highly variable and often deeply ingrained, with many convinced that less than one stool per day is a serious problem.

A formal consensus definition is therefore used by gastroenterologists, and the label of chronic functional constipation requires two or more of the following occurring for at least 3 months of the past year: straining for at least 25% of defecations, lumpy or hard stools in 25% or more of defecations, sensation of incomplete evacuation in 25% or more of defecations, sensation of anorectal obstruction or blockage in 25% or more of defecations, manual maneuvers to facilitate passage (digital evacuation or support of the pelvic floor) in 25% or more of defecations, or fewer than three defecations per week. A practical pediatric definition is delay or difficulty in defecation present for 2 or more weeks.

Abdominal bloating and mild diffuse abdominal discomfort are common with functional constipation. Vomiting, severe pain, fever, and GI bleeding indicate more serious causes. Passage of hard stool may produce rectal bleeding, but the quantity should be small. Straining may cause dizziness, a vagal reaction, or both.

With functional constipation, the findings on physical examination should be normal other than palpation of abundant stool on abdominal or rectal examination (or both) and perhaps mild discomfort on abdominal palpation.

**Differential Diagnosis and Medical Decision Making**

Constipation is a symptom that may be secondary to a myriad of other causes, but it most often represents chronic functional constipation. Boxes 37.1 to 37.4 list the various causes of secondary constipation—GI and systemic disorders, medications, and additional causes in children.

Evaluation in the ED is focused on distinguishing potentially serious cases that warrant immediate inpatient care via a careful history (what the patient means by the term *constipation*, bowel history, and potential underlying causes, especially medications) and examination (particularly vital signs, abdominal examination, perirectal inspection, and rectal examination). With chronic symptoms, it is important to ask what precipitated today’s ED visit. New-onset constipation suggests new medications, sudden lifestyle changes, anal sphincter spasm and pain, or more serious conditions, including mass lesions and intestinal obstruction.

Signs of obvious systemic abnormalities, volume depletion, infection, peritonitis, ileus, and obstruction are important to identify early. In patients with functional constipation, abdominal examination should find only mild discomfort at most. Excessive colonic stool can often be palpated. Unlike a solid mass, stool should indent somewhat on palpation. Serial abdominal examinations are invaluable in uncertain cases. Fecal impaction, abnormal sphincter tone, and potential sources of bleeding or rectal pain may be detected on perirectal and rectal examination. Anoscopy (with topical anesthetic applied before the examination) is appropriate in patients with rectal complaints.

Red flags for a more serious acute condition include severe pain, vomiting, fever, GI bleeding, acute onset, persistent tachycardia, hypotension, and peritoneal signs. Elderly patients warrant higher clinical suspicion for worrisome causes, particularly if febrile, and extraabdominal infections may be manifested as general failure to thrive or constipation. In adults older than 50 years, anemia, weight loss, acute change in bowel habits, GI bleeding, and a family history of colon cancer or inflammatory bowel syndrome (IBS) are “alarm” findings of possible underlying malignancy or IBS and warrant early referral for endoscopy or radiographic studies.

In ED patients in whom clinical suspicion for serious pathology is low, appropriate studies are limited to basic chemistry panels (including calcium) and a complete blood count. Suspicion of an obstruction, fecal impaction, ileus, megacolon, or perforation should prompt plain abdominal films (flat and upright); serial plain films may assist in diagnosing early obstruction when the initial evaluation is unclear. Emergency computed tomography (CT) scans are appropriately limited to situations suggesting obstruction, intraabdominal abscess, complicated hernia, or diverticulitis. Early surgical consultation is appropriate for probable obstruction or peritonitis.

**Considerations by Patient Age**

**Neonates**

Neonates have an increased risk for serious underlying illness or anatomic abnormalities, such as Hirschsprung disease, intestinal pseudoobstruction, imperforate anus, or hypothyroidism.
**Children**

Functional constipation is more common in boys, frequently at the time of toilet training or initial school entrance, when children withhold defecation for psychosocial reasons. A vicious cycle of difficult passage of hard stool leads to more withholding, which causes harder stool and more difficult passage. Fecal soiling (encopresis) is a common result and frequent initial symptom.

**Adolescents**

Constipation is more common in adolescent girls than boys, with the predominant symptom being straining to initiate defecation. Typically, this is a functional problem arising from chronic suppression of the urge to defecate for psychosocial reasons. An underlying eating disorder or surreptitious opiate use should also be considered.

**Adults**

Usually, adults have a chronic functional cause, including IBS. Extreme functional constipation (two or fewer stools per month) is almost exclusively seen in young women.

**Elderly Institutionalized Patients**

Mental confusion, immobility, poor oral intake, limited toileting opportunities, and medications all contribute to a high prevalence of chronic constipation and high risk for fecal impaction. Impaction is the most common cause of fecal incontinence and may lead to stercoraceous ulceration or perforation of the colon.

---

**CONSIDERATIONS BY CAUSE**

**Anatomic and Structural Causes**

Examination may reveal anatomic or muscular anomalies or masses (neoplasm, fecaloma, abscess, hernia, closed or trapped loop of bowel, rectocele) that may cause blockage. Other structural causes are painful rectal disorders, intussusception, volvulus, and adhesions. Lower spinal cord injury may produce constipation or incontinence (or both); with high cord injuries the colonic reflexes usually remain intact, although digital rectal stimulation is often needed to initiate defecation.

**Medications**

An accurate and complete list of medications (prescription, nonprescription, and alternative) should be established because so many cause or exacerbate constipation. Classic scenarios include elderly patients taking multiple prescription drugs, recreational users of opiates, and patients with acute painful injuries who were prescribed opiates without stool softeners.

**Systemic Illnesses**

A long list of metabolic, endocrine, and neurogenic disorders may secondarily produce constipation. These conditions are usually obvious from the history, physical examination, and basic laboratory studies, so extensive diagnostic searches are rarely appropriate in the ED setting.

**Functional Constipation**

In the vast majority of patients, constipation has an idiopathic functional cause related to psychosocial stressors, unintentionally learned rectal dysfunction, and lifestyle habits such as dietary fiber intake, fluid intake, and toileting. About 25% of patients have a component of pelvic dys synergy. IBS is a common functional dysmotility disorder characterized by intermittent abdominal pain, distention, and variable diarrhea or constipation with no structural lesions found; concomitant upper GI symptoms and pelvic dyssynergy are common.

Diagnosis is inexact because no specific diagnostic tests are available, but the constipation usually responds to bulk agents. Similarly, the label of chronic functional constipation is a clinical one, but exact diagnosis is not needed in the ED setting.

---

**TREATMENT**

Intravenous fluid repletion with correction of electrolyte disturbances is the mainstay of initial management in sicker patients. Suspected mechanical obstruction or perforation warrants immediate surgical consultation and admission. Intravenous fluids and analgesics are warranted, whereas laxatives are contraindicated. Patients with nausea or vomiting need antiemetics. Those with obstruction or ileus may benefit from nasogastric suctioning, plus an intravenous gastric acid blocker to prevent metabolic alkalosis. Large bowel obstruction may require early colonoscopy with decompression.

Patients with pseudoobstruction warrant inpatient care unless they are known to have chronic intermittent pseudoobstruction with only a mild exacerbation of their constipation. For acute megacolon from colonic pseudoobstruction, the prokinetic neostigmine is a standard therapy, but this is usually ordered by the gastroenterologist and followed by decompressive colonoscopy. Prokinetic agents are contraindicated in patients with obstruction, perforation, or peritonitis.

Fecal impaction may complicate long-standing constipation, particularly in nursing home residents or opiate users. Initial cleansing in milder cases may be done safely with large-volume oral polyethylene glycol (PEG), which is done in many nursing homes. Others usually require initial digital disimpaction, as discussed later, followed by PEG cleansing and then a maintenance plan. ED time constraints may prompt admission to an observation unit for initial cleansing.

For patients with uncomplicated constipation, the starting point in the ED focuses on volume repletion and electrolyte correction as needed, followed by a bowel regimen appropriate for the level of fecal loading, plus any treatment specific to contributing causes. The EP should also consider whether pelvic floor dysyn ergy is a probable component that the patient should discuss with a primary care physician. The clinician should keep in mind the problem that bothers the patient the most (infrequency, straining, or hard stool) and that the patient’s expectations often include prescription “cures” and an unrealistic goal of rapidly becoming “normal.” Patient education is vital.

The plan for bowel care includes:

- Initial cleansing (usually laxatives, both oral and rectal)
- Maintenance plan (increase fluid and fiber intake, consideration of laxatives or softeners)
- Behavioral modification (diet, toilet habits, exercise)
- Other interventions tailored to the suspected underlying cause or causes
Most patients are sent home with a management plan and education, but initial cleansing in the ED or observation unit and serial reexamination should be considered if a suspicion remains about a more serious underlying cause or if the patient may not be able to perform the initial steps (or has no reliable caretaker to do so). A myriad of products are available for constipation (Table 37.1).

Selection should focus on efficacy, safety, and cost, as well as patient preference.

If ED cleansing is necessary, time constraints prompt the use of osmotic laxatives per rectum, either suppositories (glycerin or bisacodyl) or enemas (tap water or phosphate). A topical anesthetic gel will decrease defecatory pain. Digital disimpaction may speed the process but is generally reserved as a last resort. Digital stimulation (several gentle rotations of a gloved, well-lubricated finger within the rectum) may loosen up fecal concretions and stimulate spontaneous defecation; this may be repeated after a 10-minute pause. If no response is seen, the lumps will need to be gently broken up and removed by finger. In spinal cord or elderly patients, the pulse and blood pressure should be monitored during disimpaction for changes secondary to vagal stimulation or autonomic dysreflexia.

Outpatient treatment should start with osmotic laxatives such as PEG to be taken at home or just bulk agents, prune juice, or dried prunes if the constipation is mild. A stimulant laxative (e.g., glycerin suppository) is to be taken if the simpler treatment fails. Strong evidence supports the use of PEG, moderate evidence supports lactulose and psyllium, and little evidence exists for or against other agents. In the elderly, all laxative categories may cause some bloating, flatulence, or abdominal pain.

Bulk agents are the first-line maintenance treatment of functional constipation with a normal or slow transit time. Bulk agents increase fecal water content and stool volume, reduce transit time, and improve stool consistency. Bran fiber (25 g/day) in foods may be adequate and must be accompanied by increased fluid intake. fiber may cause increased gas (bloating, flatulence), but this is less likely if intake is increased gradually.

The stool softeners sodium and calcium docusate decrease surface tension and allow stool to mix with fluids but do not induce defecation. These agents are not good for long-term use because of tachyphylaxis, but they are very useful in the short term while taking constipating medications (e.g., opiates) or for patients who should avoid straining.

Lubricant agents penetrate and soften stool. Mineral oil can be given orally or by enema. Because it may be aspirated and cause lipid pneumonia, it should not be used in patients with esophageal dysmotility, dysphagia, or gastroesophageal reflux.

Osmotic laxatives are hyperosmotic agents that generally provide excellent relief of constipation and may be used in small doses for the long term if needed. A large volume of PEG is used for procedural preparation or initial cleansing of large fecal loads, but most cases of constipation respond to one packet (17 g) daily, which may be continued as a maintenance dosage; PEG without electrolytes is more palatable. Lactulose and sorbitol (given orally or as enemas) are nonabsorbable sugars degraded by colonic bacteria to acids that increase stool acidity and osmolarity and thereby lead to accumulation of fluid in the colon to speed defecation. Lactulose is excellent for long-term use in small doses but should be avoided in most diabetics. Corn syrup is used in infants.

Stimulant laxatives are the most rapidly acting agents and are taken either orally or per rectum (faster). They are likely to cause some cramping. Saline cathartics exert osmotic effects to increase intraluminal water content. Though relatively nonabsorbable, magnesium preparations should be avoided in patients with renal failure because they may cause hypermagnesemia or fluid retention. Castor oil is hydrolyzed to ricinoleic acid, which stimulates intestinal secretion and motility. Bisacodyl causes fluid accumulation and increased motor activity. Anthraquinones (cascarilla, senna) are converted to active states by intestinal microorganisms and increase fluid and electrolyte accumulation in the distal end of the bowel; melanosom coli may result from long-term use but is benign and reversible. Stimulants are not generally recommended for frequent long-term use.

General measures often help:

- Higher intake of fluids (≥2 L daily) and fiber
- Greater physical mobility and exercise (brisk daily walk)
- Dedicated and unhurried time for defecation

Dietary fiber sources are primarily bran and grains, but dried fruits, pulp-rich citrus juices, many vegetables, and even popcorn contribute fiber. Retraining bowel habits may help; patients must allow an unhurried time (20 minutes or so) to use the toilet, especially after a meal (breakfast is ideal) to take advantage of the gastrocolic reflex, and they should respond to the urge to defecate. Contributing medications require careful review of their necessity, planned duration of use, and alternatives. For drugs that must be continued, increased fiber and the addition of stool softeners may suffice, with daily PEG or lactulose added if needed. Bulk agents may affect the bioavailability of some drugs. The EP must communicate clearly to the patient that the constipation is a side effect of medications that needs to be discussed with the primary care provider.

Concomitant treatment of underlying causes and contributors is essential. Treatment of painful rectal problems improves overall bowel function. Although they are not generally prescribed in an ED setting, other treatments are available. Lubiprostone is a bicyclic fatty acid that activates GI chloride channels to increase intestinal fluid secretion and effectively treats chronic functional constipation. Even in the elderly, pelvic floor dyssnergy may respond well to physical therapy, behavioral modification, and biofeedback training. Surgery may relieve specific defects, such as rectoceles, and is the mainstay for treatment of Hirschsprung disease.

FOLLOW-UP CARE AND PATIENT EDUCATION

ADMISSION

Indications for admission are limited to patients with obstruction, pseudoobstruction, severe electrolyte disturbances, or other serious causes of secondary constipation. An observational stay may be appropriate for those with an inability to

safely perform initial bowel cleansing at home or those with moderate clinical suspicion of another underlying cause (e.g., those with persistent abdominal pain or low-grade fever without obvious cause).

FOLLOW-UP
Follow-up primary care visits are adequate discharge planning for most patients. Those with obvious structural causes (e.g., hemorrhoids, rectoceles) or high suspicion for causes such as spinal cord pathology, Hirschsprung disease, and other conditions, warrant specialty referral. Outpatient studies of colorectal structure (e.g., colonoscopy) are appropriate for those older than 50 years as cancer screening and are necessary for patients of any age with alarming signs or symptoms (acute and unexplained onset, weight loss, bleeding, iron deficiency anemia). However, structural studies do not provide an assessment of functional constipation, and few patients need functional studies; clinical response to treatment and further needs are better judged with ongoing primary care.

PATIENT EDUCATION
Patient education is crucial. Patients are often frightened and disturbed by symptoms that the physician may take lightly; reassurance and discussion are invaluable. As appropriate, the EP should explain that cancer or other serious disease is highly unlikely but that compliance with follow-up remains essential. The patient should be taught about “normal” bowel function, general measures to improve symptoms, and reasonable goals. The EP and nurse must also ensure that patients know how to use the items recommended, especially suppositories or enemas.34

COMPLICATIONS AND PITFALLS
Although constipation is straightforward in most patients, certain potential pitfalls need to be avoided. Determination of exactly what the patient means by the word constipation is important, as are realistic goals for those with chronic constipation. Reassurance and patient education with specific treatment and follow-up instructions are essential in functional constipation cases, particularly in adults to avoid missing an opportunity for outpatient screening with early diagnosis of an underlying malignancy. Failure to recognize obstruction is often avoidable with serial reexaminations over a 4- to 6-hour period and by observing the patient after food intake. Unrecognized fecal impaction can lead to GI bleeding, mucosal ulceration, or even perforation; negative findings on rectal examination do not rule out a higher impaction, so plain radiographs are appropriate if suspicious. Overly aggressive digital disimpaction may lead to bacteremia; not all reachable stool pellets need to be removed at a single time when follow-up with PEG will clear the rest. Fever in an elderly patient is not explained by constipation. In children, a careful perirectal and rectal examination is difficult, but otherwise it is easy to overlook an anal fissure. In women of childbearing age (including perimenopausal), a pregnancy test is necessary, especially before consideration of a CT scan or outpatient radiographic colonic study.

PATIENT TEACHING TIPS

Functional Constipation
General Concepts
Goals: bowel movements three or more times per week, pain-free, with minimal straining.
Daily bowel movements are not needed.
The long-term prognosis is excellent and serious diseases such as cancer are not likely, but outpatient follow-up is always important to see how you are doing and whether other tests may be needed.
If constipation is long-standing, return to “normal” bowel habits may take several weeks.
Keep a bowel diary (brief description of food and fluid intake, bowel movements, problems) for 1 to 2 weeks to review with your primary care doctor.

Recommended Medications and Laxatives
Follow the plan recommended by your physician today.
Short-term use of strong laxatives for the next few days is OK for initial cleansing, but avoid long-term use unless your primary care doctor advises you to do so.
Small daily doses of osmotic laxatives such as lactulose or polyethylene glycol may be needed for a few weeks, along with bowel retraining.

Healthy Bowel Habits
Visit the toilet every day after the meal of your choice (breakfast is best), and sit for 15 to 20 minutes:
Relax, do not hurry, and do not strain.
Try for about the same time every day.
Do respond to the urge to defecate.
Drink at least 2 L of fluids (without caffeine or alcohol) daily to stay well hydrated.
Gradually increase your fiber intake (bran, high-fiber cereals, fruits, vegetables, or nonprescription fiber products such as psyllium) to about 25 g/day.
Note whether milk or milk products aggravate your symptoms.
Regular exercise (walking) may help stimulate improved bowel movements.

REFERENCES

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

Incisional hernias of the abdominal wall occur in up to 11% of all other postoperative patients and in as many as 23% of patients with postoperative wound infections. Trocar site hernias after laparoscopic surgery are reported in up to 6% of patients. Parastomal hernia formation occurs in 28% of ileostomies and 48% of colostomies. Morbidity depends on the location and contents of the hernia, as well as the development of incarceration or strangulation.

PATHOPHYSIOLOGY

Hernias are congenital or acquired defects in the abdominal wall that allow protrusion of intraabdominal contents through the pathologic opening. The characteristic finding consists of pain and swelling at the hernia site. Intraabdominal hernias, which can occur spontaneously or after surgery or trauma, are caused by defects in the diaphragm, mesentery, or ligamentous structures.

Incarcerated hernias are those in which abdominal contents have become trapped in the opening (i.e., nonreducible). Bowel incarceration can be manifested as pain, vomiting, or frank obstruction.

Strangulated hernias involve a compromise of the blood supply to the hernia contents. Strangulation can be manifested as fever, ischemia, or necrosis of the hernia contents and, occasionally, erythema or necrosis of the skin overlying the hernia. Smaller defects in the abdominal wall are more likely to be manifested as incarceration or strangulation.

Reduction—replacement of the hernia contents back into the abdominal cavity—is the immediate treatment of a hernia. Reduction of a hernia is accomplished by gentle pressure over the area of herniation. Reduction is assisted by use of the supine or Trendelenburg position, application of ice, analgesia, and procedural sedation to relax the musculature of the abdominal wall. Reduction should not be attempted if necrosis of the hernia contents is suspected. Definitive hernia treatment is surgical repair.

NOMENCLATURE

Table 38.1 and Box 38.1 summarize the nomenclature of hernias, and Figures 38.1 to 38.13 illustrate some of the hernia types.

BOX 38.1 Eponyms Associated with Hernias

- Richter hernia (partial enterocoe): Herniation of only the anterior surface of the intestinal wall through the hernia defect; accounts for 10% of strangulated hernias
- Amyand hernia: Acute appendicitis in the sac of an inguinal hernia
- Garengeot hernia: Acute appendicitis in the sac of a femoral hernia
- Littre hernia: Strangulated Meckel diverticulum in a hernia sac
- Maydl hernia: Internal hernia with double-loop strangulation
- Chilaiditi syndrome: Symptomatic interposition of the intraabdominal contents between the liver and diaphragm; can become incarcerated
- Canal of Nuck: The portion of the processus vaginalis that accompanies the round ligament through the inguinal canal in women; may contain hernia contents or, rarely, hydrocele in women
- Romberg-Howship sign: Lancinating pain along the inner side of the thigh to the knee or down the leg to the foot caused by compression of the obturator nerve in cases of incarcerated obturator hernia

CHAPTER 38  HERNIAS

**PATHOPHYSIOLOGY**

In comparison with controls, patients in whom incisional or recurrent hernias develop may exhibit abnormal synthesis of type I and type III collagen. A higher incidence of incisional hernia formation is seen in patients with wound infection, obesity, and multiple comorbid conditions. The use of synthetic mesh and “tension-free” repair techniques has reduced rates of hernia recurrence.

**PRESENTING SIGNS AND SYMPTOMS**

The classic manifestation of an abdominal wall hernia is pain and swelling at the hernia site. Symptoms are more pronounced with increased intraabdominal pressure, such as occurs with standing, coughing, and straining. Occasionally, patients report an acute onset of symptoms after heavy lifting or during sports. Many patients observe that the swelling (“lump” or “knot”) resolves when they are supine or pressure is applied over the area.

Inguinal hernias can be manifested as scrotal pain, a groin mass, or swelling. Incarcerated hernias typically feature a painful lump or knot on the abdominal wall or in the scrotum. The hernia is very tender to palpation and is not reduced by gentle pressure. If small bowel is incarcerated in the hernia sac, the patient may exhibit nausea and vomiting. Incarcerated omentum or preperitoneal fat may give rise to only a localized painful mass.

**RED FLAGS**

Symptoms that suggest hernia complications (obstruction, incarceration, or strangulation) are as follows:
- Diffuse rather than localized pain and tenderness with guarding or rebound
- Nausea or vomiting
- Markedly tender, nonreducible hernia
- Fever
- Erythema or necrosis of the skin overlying the hernia

**LUMBAR HERNIAS**

![Fig. 38.6 Locations of lumbar hernias.](image-url)

Fig. 38.9 Morgagni-type diaphragmatic hernia manifested as an abnormal cardiac silhouette (arrow). (From Daneshvar S, Shriki J, Sohn H, et al. Morgagni-type diaphragmatic hernia presenting as an abnormal cardiac silhouette. Am J Med 2010;123:e11-2.)

Fig. 38.10 Computed tomographic scan of a diaphragmatic hernia. (From Yang YM, Yang HB, Park JS, et al. Spontaneous diaphragmatic rupture complicated with perforation of the stomach during Pilates. Am J Emerg Med. 2010;28:259.e1-3.)
As the incarceration persists over time, swelling of the hernia contents eventually compromises the blood supply and strangulation ensues. The signs and symptoms vary with the contents of the hernia. Patients with incarcerated intestine leading to intestinal ischemia or necrosis may have fever and peritonitis. Prolonged incarceration with necrosis of the hernia contents may cause erythema or necrosis of the skin overlying the hernia.

Long-standing hernias may feature very large defects in the abdominal wall. In general, larger defects are less likely to be manifested as strangulation. A large hernia may be chronically incarcerated or nonreducible. With time, fibrous adhesions develop and prevent spontaneous reduction when the patient is supine.

Less typical findings include ill-defined abdominal pain, nausea, and vomiting but without an obvious mass on the abdominal wall. This manifestation is more likely to occur with intraabdominal hernias, in obese patients, or in patients who are unable to give an adequate history.

The incidence of postoperative internal hernias is rising because of the increase in bariatric operations in the United States, particularly Roux-en-Y gastric bypass. Postoperative complications of hernia repair include wound infection, seroma or hematoma, ileus or small bowel obstruction, recurrence of the hernia, and in rare cases, erosion of preperitoneal mesh into intraabdominal organs with associated fistula formation. Complications of inguinal hernia repair are chronic pain as a result of nerve disruption or entrapment and, rarely, testicular ischemia.

Traumatic diaphragmatic disruption from penetrating trauma should be suspected when the trajectory of a gunshot wound or the location of a stab wound potentially crosses the diaphragm. Though rare, diaphragmatic disruption can occur after significant blunt trauma and is more common on the left side. Traumatic diaphragmatic disruption is difficult to diagnose in the acute stage because of nonspecific signs, but it should be suspected when the patient has a proximate injury and pain out of proportion to the physical findings. Standard imaging techniques, including chest and abdominal computed tomography (CT), may miss small diaphragmatic injuries, and laparoscopy, thoracoscopy, or surgical exploration may be required.

Diaphragmatic disruption has also been described after forceful coughing or vomiting. Delayed manifestations of diaphragmatic hernias consist of chest pain, dyspnea, or abnormal findings on chest radiography or CT (with or without abdominal symptoms). The use of multidetector CT scanning has improved the detection of diaphragmatic hernias.
DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis of abdominal wall hernias includes other masses involving the abdominal wall, such as lipomas and rectus sheath hematomas. Abdominal wall or intraabdominal hernias should be considered a potential cause in patients with signs and symptoms of small bowel obstruction. In patients who have previously undergone abdominal surgery, either open or laparoscopic, careful examination of the incisions, trocar sites, and parastomal areas should be performed to detect masses or abdominal wall defects. To facilitate detection of the hernia, the examiner should hold the tips of the fingers over the incision while the patient coughs or strains.

Inguinal hernias should be considered in the evaluation of patients with scrotal pain or swelling. Detection of inguinal hernias is improved by examination of the patient in a standing position and insertion of the examiner’s finger into the inguinal canal through the loose skin of the scrotum. This technique allows direct palpation of the inguinal ring. Having the patient cough or strain allows the examiner to palpate the hernia bulging against the examining finger. Other causes of scrotal pain, masses, or swelling include testicular torsion, tumor, orchitis, epididymitis, lipoma, hydrocele, and varicocele.

Congenital anatomic fistulas of the urachus or omphalomesenteric duct can be manifested in children or adults as umbilical pain, swelling, a mass, erythema, or discharge and can be confused with an umbilical hernia.

Obturator or other rare pelvic floor hernias should be considered in the differential diagnosis of patients with chronic atypical pelvic pain; CT should be performed.

DOCUMENTATION

Physical examination
Ultrasound, especially for scrotal hernias
Computed tomography when internal hernia, small bowel obstruction, intestinal ischemia, or necrosis is a concern
Rarely magnetic resonance imaging or laparoscopy

In the majority of cases, physical examination alone enables the identification of abdominal wall or inguinal hernias. When physical examination is not sufficient, ultrasonography, CT, and occasionally magnetic resonance imaging can assist in the identification of hernias and serve to further delineate their contents.

Ultrasonography is the imaging modality of choice in the evaluation of scrotal swelling or masses because it allows differentiation of the testicles, spermatic cord, hydrocele, or varicocele separately from the hernia contents. This modality can assist in the diagnosis of abdominal wall hernias through identification of bowel loops within the hernia sac. Color flow Doppler imaging can detect the presence or absence of blood flow in some cases, thereby aiding in the diagnosis of strangulation.

CT can be used to identify intraabdominal and abdominal wall hernias (as well as delineate the contents of the hernia sac) and signs of ischemia, perforation, or abscess formation. Plain abdominal films have limited utility in the diagnosis and evaluation of hernias. Laparoscopy may be necessary to assist in the diagnosis of difficult cases when the findings of other modalities are unrevealing.

PEDEATRIC CONSIDERATIONS

Omphalocele occurs in 2 to 3 per 10,000 births. Historically, gastroschisis occurred less frequently than omphalocele, but recent trends show an increase in the incidence of gastroschisis worldwide (and in the United States). Gastroschisis occurs more commonly with younger maternal age and is associated with fewer congenital anomalies than omphalocele is. Ultrasonography has led to more frequent prenatal diagnosis, but cesarean delivery has not been shown to improve outcomes over vaginal delivery in infants with abdominal wall defects.

Congenital diaphragmatic hernias occur in 1 in 2500 births. The mortality rate is high because of pulmonary hypoplasia and the development of pulmonary hypertension. Ultrasonography allows prenatal diagnosis and identification of infants with the potential for a poor prognosis. The prognosis worsens when the liver is located intrathoracically and total lung volume is less than total head volume. In utero repair of diaphragmatic hernias has been performed, although better outcomes than those with conventional treatment have not been observed.

Percutaneous placement of a fetal endoluminal tracheal occlusion balloon may improve survival by preventing egress of the pulmonary fluid needed to stimulate lung growth. This treatment is still controversial because of a higher incidence of preterm labor. Stabilization of infants with congenital diaphragmatic hernia consists of intravenous fluid resuscitation, insertion of a nasogastric tube, intubation with gentle ventilation or permissive hypercapnia (to avoid barotrauma), and surgical consultation. The use of nitric oxide and surfactant has not been demonstrated to improve outcomes in infants with congenital diaphragmatic hernias.

Late manifestations of congenital diaphragmatic hernia have been described in children and adults. Cases typically involve respiratory difficulty, and tension gas trothorax has also been reported. Unrecognized diaphragmatic hernias can be exacerbated by pregnancy and be manifested as incarceration and bowel obstruction, in addition to respiratory distress.

Indirect inguinal and umbilical hernias are extremely common in children—parents may bring an infant or child to the emergency department when the lump or bulge is first noted. Incarceration or strangulation is uncommon but can occur. The clinical findings in children are similar to those in adults. Physical examination of the scrotum and groin is mandatory in the evaluation of crying or vomiting infants. Ultrasonography is used more often than CT for the evaluation of hernias in children.

TREATMENT

HOSPITAL

Reduction of the hernia is attempted by applying slow gentle pressure over the hernia contents and directing the contents
Reduction should not be attempted when the patient has signs of peritoneal irritation, fever, or erythema or necrosis of the skin overlying the hernia. These signs signal the possibility of necrotic bowel, reduction of which could lead to diffuse peritonitis and abscess formation. When bowel ischemia or necrosis is suspected, antibiotics that cover intraabdominal pathogens should be administered and surgical consultation obtained.

Patients with signs of volume depletion or sepsis should receive fluid resuscitation with normal saline. Urine output should be monitored via catheter placement to help to guide fluid replacement. A nasogastric tube should be placed in patients with signs of bowel obstruction.

The current surgical trend is toward laparoscopic repair of most hernias.13 Laparoscopic repair of incisional hernias tends to decrease perioperative pain and recovery time and has complication and recurrence rates similar to those with open repair.14 Laparoscopic inguinal hernia repair has a slightly higher incidence of bladder and vascular injury than open repair does.15

Postoperative complications of hernia repair include bowel injury, hemorrhage, wound infection, and recurrence. The use of prosthetic mesh has decreased hernia recurrence, although mesh is problematic when wound infection occurs. Late complications of the use of prosthetic mesh for hernia repair consist of fibrosis and erosion into adjacent structures, including bowel and bladder, and occasionally fistula formation.16 Other complications of inguinal hernia repair are entrapment of the genitofemoral or ilioinguinal nerves, persistent pain syndromes, and in male patients, injury to the vas deferens and testicles with resultant alterations in fertility.17 Repair of abdominal wall hernias can injure cutaneous nerves and give rise to persistent abdominal wall pain syndromes.18

Hernias with signs or symptoms suggestive of bowel obstruction or ischemia are true surgical emergencies that require immediate consultation.

Emergency repair of incarcerated or strangulated hernias is associated with higher morbidity and mortality than is the case with elective repair, especially in elderly patients or those with multiple medical comorbid conditions.19 Complications include a higher incidence of bowel ischemia and necrosis, wound infection and dehiscence, intraabdominal compartment syndrome, sepsis and respiratory compromise, and hernia recurrence.20

Patients with easily reducible hernias may be discharged for surgical follow-up and elective hernia repair. Repair is generally recommended for symptomatic hernias in otherwise healthy patients. Patients who have multiple medical problems and for whom surgery poses a high risk may not be suitable candidates for elective hernia repair, especially when the fascial defect is large and less likely to become incarcerated. The decision about the timing of hernia repair should be made by the patient in conjunction with the primary care physician and the surgeon. Elective repair of symptomatic hernias in elderly patients should be considered.21

Unrepaired hernias may gradually enlarge over time, and some become incarcerated. Patients with incarcerated hernias that cannot be reduced should be admitted for urgent surgical reduction and repair because some hernias progress to ischemia of the hernia contents.

### TIPS AND TRICKS

To reduce a hernia through a small defect, it may be wise to pull on the hernia instead of pushing. Imagine a balloon trying to pass through a small hole—direct pressure on the balloon flattens the mass rather than pushing it through the hole. Instead, pressure applied at the defect in the abdominal wall (the base of the hernia) with accompanying traction on the herniated contents can narrow the sac and facilitate passage. The emergency physician should apply horizontal pressure with the tips of the fingers to narrow the base of the herniated contents while gently pulling the herniated mass. Pulling on the hernia from the base may be more successful than pushing.

### PRIORITY ACTIONS

- Analgesia, fluid resuscitation, attempts at manual reduction of the hernia, and procedural sedation should be used as necessary.
- Complications of persistent hernia incarceration include small bowel obstruction, bowel ischemia, or necrosis of the hernia contents.
- Surgical consultation should be obtained for possible operative intervention in cases of persistent incarceration, small bowel obstruction, bowel ischemia or necrosis.

### DOCUMENTATION

- Presence or absence of a palpable hernia mass or fascial defect with estimation of size
- Presence or absence of erythema or necrosis of the overlying skin
- Presence or absence of fever, signs of small bowel obstruction
- Presence or absence of guarding or rebound
- Name of consultant, time of consultation
PATIENT TEACHING TIPS

A hernia is a defect in the abdominal wall that allows the intestines or abdominal fat to bulge through the opening. Hernias do not typically heal spontaneously and may enlarge over time. They may be repaired by surgery.

Sometimes the contents of the hernia may become trapped or incarcerated, which is potentially dangerous because the blood supply to the contents of the hernia may be cut off. You should return to the emergency department if your hernia suddenly becomes larger or more painful or if fever, nausea, vomiting, or redness over your hernia develops; if any of those things happen, your hernia would need to be treated right away.

Appendicitis
Rita A. Manfredi and Claudia Ranniger

KEY POINTS

- Appendicitis is the most common abdominal surgical emergency in the United States.
- Physical signs and symptoms vary with the location of the appendix.
- Children, pregnant women, and elderly patients may exhibit subtle clinical findings.
- No single diagnostic test can reliably confirm or exclude appendicitis.
- Early surgical consultation should not be delayed for diagnostic testing.
- Protocols involving ultrasound and then computed tomography can decrease radiation exposure in patients requiring diagnostic imaging.
- Narcotic analgesia does not interfere with diagnostic accuracy.
- Prophylactic antibiotic therapy, properly timed, decreases postoperative infection rates.

ANATOMY

The appendix is a tubular structure that arises from the cecum and consists primarily of smooth muscle and an abundance of lymphoid tissue. The average adult appendix can reach a length of 10 cm with a luminal width of 6 to 7 mm. Innervation from sympathetic and vagus nerves accounts for referred pain to the umbilicus when inflammatory changes are present. The location of the appendix (retrocecal, 65%; pelvic, 31%; subcecal, 2%) determines the clinical findings and risk for the development of perforated appendicitis.

PATHOPHYSIOLOGY

Acute appendicitis develops as a result of luminal obstruction, which promotes bacterial overgrowth and distention. Obstruction of the appendiceal lumen is commonly caused by fecal stasis and fecaliths; other obstructive masses include lymphoid hyperplasia, vegetable matter, fruit seeds, intestinal worms, inspissated radiographic barium, and tumors (e.g., carcinoid). Luminal obstruction creates a closed space in which bacterial overgrowth leads to the accumulation of fluid and gas. Organisms are typically polymicrobial, with a predominance of anaerobic and gram-negative species.

As the appendix distends, normal circulatory supply is impaired and the inflammatory changes worsen. Ischemia, infarction, and perforation can ensue. Progression of an inflamed appendix from gangrene to perforation is variable, with a mean duration of abdominal symptoms of between 2 days (gangrene) and 3 days (perforation).

CLINICAL PRESENTATIONS

CLASSIC

The pain of acute appendicitis starts as diffuse, poorly localized, periumbilical discomfort (visceral pain) that localizes to the McBurney point in the right lower quadrant over a period of 12 to 24 hours (peritoneal pain). The McBurney point is located one third of the distance from the right anterior superior iliac crest to the umbilicus. The appendix is located within 5 cm of the McBurney point in only 50% of patients.

Once the pain is perceived in the right lower quadrant, sudden movements cause severe discomfort consistent with localized peritonitis. Associated symptoms often include anorexia, nausea, and vomiting. Diarrhea is uncommon, although patients may report an increasing urge to defecate (the “downward urge”). Bowel movements or the passage of flatus does not relieve the pain, however.

EPIDEMIOLOGY

About 1% of patients seeking care in the ED for abdominal pain have appendicitis, and missed diagnosis and subsequent morbidity continue to occur. The lifetime risk for appendicitis is approximately 9% in men and 7% in women. The classic “textbook” manifestation of appendicitis—right lower quadrant pain, abdominal rigidity, and migration of pain from the periumbilical area to the right lower quadrant—is the exception rather than the norm. Symptoms are frequently atypical, and subtle findings are common. Delayed diagnosis results in a higher risk for perforation, which increases morbidity and mortality. When the diagnosis is delayed, about 20% of appendicitis cases perforate.
Appendicitis is the most common condition requiring emergency abdominal surgery in children. Up to 8% of children seen in the ED with abdominal pain have appendicitis. In the very young, appendicitis is quite uncommon because the appendix is funnel shaped and less prone to obstruction. Symptoms of appendicitis in this age group are nonspecific and mimic those of gastroenteritis, viral syndrome, and intussusception. The incidence of appendicitis rises with age, but the likelihood of perforation is highest in infants. Neonatal appendicitis has a high mortality rate. Almost 100% of children younger than 2 years have a perforated appendix at the time of diagnosis. In children 3 to 5 years of age the perforation rate is 71%, and in children 6 to 10 years of age the rate is 40%. Appendicitis most frequently occurs in patients between 10 and 20 years old.

Children with appendicitis commonly exhibit fever and vomiting. These two signs, along with abdominal distention, are most often seen in infants. A lethargic, irritable baby with grunting respirations may be a typical manifestation in this age group. Toddlers are more likely to have vomiting and fever followed by pain. In school-age children, vomiting and abdominal pain are the more frequent symptoms. When the diagnosis is unclear, one should avoid diagnosing acute gastroenteritis in young children without diarrhea.

In the vast majority of children, the diagnosis of appendicitis is made only after perforation occurs, possibly because of a child’s inability to describe the pain or the physician’s misattribution of symptoms to other childhood diseases or to gastroenteritis. As a result of perforation, worsening peritonitis in children might be manifested as lethargy, inactivity, and hypothermia.

Adolescent girls are a subset of the pediatric population that deserves special attention in the evaluation of acute appendicitis. The etiology of right lower quadrant pain in prepubertal and postpubertal girls includes ovarian torsion, ovarian cyst, intrauterine pregnancy, and ectopic pregnancy. A urine pregnancy test followed by pelvic ultrasonography may be helpful in distinguishing ovarian pathology from appendicitis.

**Elderly**

Elderly patients are often initially seen late in the course of the disease and are three times more likely than the general population to have perforated appendicitis. The elderly have a higher incidence of early perforation (up to 70%) because of the anatomic changes in the appendix that occur with age, such as thinner mucosal lining, decreased lymphoid tissue, a narrowed appendiceal lumen, and atherosclerosis. A definitive diagnosis is often difficult to make because of associated comorbid conditions and the possibility of immunosuppression. Appendicitis accounts for 7% of abdominal pain in the elderly. Geriatric patients most commonly have an atypical manifestation and delay seeking medical intervention. In patients older than 70 years, the mortality rate is higher than 20% because of diagnostic and therapeutic delays. The majority of older patients with acute appendicitis are afebrile and do not have leukocytosis. When the clinical, laboratory, and imaging findings are equivocal, a low threshold for surgical consultation and inpatient observation must be considered for elderly patients with abdominal pain.

**Pregnant Women**

Appendicitis is the most common extrauterine surgical emergency during pregnancy. Diagnosis of appendicitis in pregnancy is difficult because the appendix migrates upward as the uterus enlarges, so the location of pain or tenderness is variable. Early symptoms of appendicitis, particularly nausea and vomiting, are common in pregnancy. Leukocytosis is also a normal finding in pregnancy and does not aid in the differentiation of appendicitis, although an increase in band cells implies the presence of infection.

Pregnancy appears to have a protective effect on the development of appendicitis, especially in the third trimester. A fetal loss rate of up to 5% is seen in patients with unruptured appendicitis. Maternal death from appendicitis is extremely rare; however, perforation and subsequent peritonitis cause fetal mortality to rise to 30% and maternal mortality to 2%. The use of ultrasonography may differentiate obstetric causes of abdominal pain from appendicitis without the need for imaging studies that involve radiation, such as computed tomography (CT). Once the diagnosis of appendicitis has been made in a pregnant patient, urgent surgical exploration should be performed.

**Nonpregnant Women**

Gynecologic causes of lower abdominal pain often mimic appendicitis. Up to 45% of women who appear to have appendicitis on clinical examination are found to have a normal appendix at surgery. The highest percentage of misdiagnosis occurs in women of childbearing age.

**DIFFERENTIAL DIAGNOSIS**

When a patient complains of abdominal pain, suspicion for appendicitis, whether high or low, should be present in the
Table 39.1 Special Maneuvers That Suggest Appendicitis

<table>

clinician’s thought. The differential diagnosis for acute appendicitis is extensive and includes all causes of an acute abdomen (Box 39.1). Given that atypical manifestations in children, pregnant women, and the elderly are not uncommon, a high index of suspicion and early surgical consultation are critical.12

**BOX 39.1 Differential Diagnosis of Acute Appendicitis**

**Women**
- Pelvic inflammatory disease and salpingitis
- Ruptured ovarian cyst
- Ovarian and adnexal torsion
- Endometriosis
- Ectopic pregnancy
- Tuboovarian abscess

**Men**
- Testicular torsion
- Epididymitis and orchitis

**Men and Women**
- Nephrolithiasis
- Urinary tract infection and pyelonephritis
- Diverticulitis
- Inflammatory bowel disease (terminal ileitis in Crohn disease)
- Infectious enteritis and colitis
- Incarcerated hernia
- Mesenteric adenitis

**Elderly Patients**
- Diverticulitis
- Mesenteric ischemia
- Vascular disease

**DIAGNOSTIC TESTING**

No single diagnostic test can reliably confirm or exclude the diagnosis of appendicitis. Diagnostic testing should not delay surgical consultation for patients with worrisome findings on examination. The surgeon should be engaged immediately (before laboratory testing or imaging) for a patient with an acute abdomen or when appendicitis is the most likely clinical diagnosis (Box 39.2).

The goals of testing are to improve accuracy and speed of diagnosis, exclude alternative causes of abdominal pain, and reduce the rate of appendectomies performed in patients who have a normal appendix (negative appendectomy rate).

**LABORATORY TESTING**

Elevations in the white blood cell (WBC) count, percentage of bands, absolute neutrophil count, and C-reactive protein (CRP) level have each been associated with a greater likelihood of appendicitis. Taken individually, these tests have poor predictive value.7 In combination, elevated WBC and CRP values have been associated with positive likelihood ratios between 7 and 23 for the prediction of appendicitis in both children and adults.13,14 The likelihood of appendicitis when both WBC and CRP values are in the normal range is low.15,16 However, CRP and WBC values vary with age and the duration of symptoms; patients who are seen early in the disease process may have a normal CRP level.

Scoring systems that include historical data, physical findings, and laboratory markers have been developed to assist in differentiating appendicitis from other sources of abdominal pain. However, the sensitivity and specificity of these systems are not sufficient to predict the presence or absence of appendicitis with adequate reliability. These tools are more frequently used to risk-stratify patients who may need further diagnostic testing or observation.17-21

It is imperative that pregnancy be excluded early in the assessment of a woman of childbearing age by checking a urine or serum quantitative human chorionic gonadotropin level.

An abnormal urinalysis result must be interpreted with caution in a patient with suspected appendicitis and a low likelihood of cystitis. Abnormal urinalysis results (including more than 4 red blood cells [RBCs] per high-power field [HPF], more than 4 WBCs per HPF, or proteinuria greater than 0.5 g/L) are observed in 36% to 50% of patients with acute appendicitis.22 These findings are more common in women, in patients with perforated appendicitis, and in patients in whom
APPENDICITIS SCORING SYSTEMS

Difficult-to-diagnose cases of appendicitis are those that are manifested atypically. Appendicitis scoring systems based on historical data, physical examination, and laboratory results have been derived to decrease diagnostic uncertainty. No single test is able to identify appendicitis reliably. The utility of the scores lies in determining which patients can be safely sent home without imaging and, conversely, which patients should go to the operating room without delay. Most scores presented here stratify the patient population into a low, indeterminate, or high probability of having appendicitis.

The measures of a score’s efficacy are its sensitivity (which documents how well the score identifies all individuals with appendicitis) and its specificity (which documents how well the score excludes those without appendicitis). The sensitivities reported here are calculated from the number of individuals with and without appendicitis when using the low-probability cutoff. The specificities are calculated from the number of individuals with and without appendicitis when using the high-probability cutoff. The measure of a score’s utility can also be assessed by the proportion of patients who remain in the indeterminate group—that is, the group that requires additional resources and imaging for diagnosis. All patients in indeterminate groups should be further evaluated either through diagnostic imaging or by observation, at the discretion of the treating clinician.

Table 39.2 presents some common appendicitis scoring systems.51-53 Table 39.3 presents cutoff values, sensitivities and specificities, and size of the indeterminate group for these same scoring systems.51-57 Please note that the scoring systems have been applied in many more settings than can reasonably be presented here and that the accuracy of the scoring systems may vary significantly by study. In particular, the Alvarado score, developed in 1986, has been studied extensively.

Sensitivities and specificities vary among studies that apply the same scoring system. Confounding variables include differences in patient age (in some pediatric studies, for example, children younger than 4 years are not included because the historical symptoms cannot be scored), differences in inclusion criteria (e.g., excluding patients with pain for more than 7 days), or differences in the prevailing rate of appendicitis in the study cohort (ranging from 20% to 80%). It is important to understand the demographics of your own patient population when applying these scoring systems.

CHAPTER 39 ▪ APPENDICITIS

APPENDICITIS SCORING SYSTEMS

Difficult-to-diagnose cases of appendicitis are those that are manifested atypically. Appendicitis scoring systems based on historical data, physical examination, and laboratory results have been derived to decrease diagnostic uncertainty. No single test is able to identify appendicitis reliably. The utility of the scores lies in determining which patients can be safely sent home without imaging and, conversely, which patients should go to the operating room without delay. Most scores presented here stratify the patient population into a low, indeterminate, or high probability of having appendicitis.

The measures of a score’s efficacy are its sensitivity (which documents how well the score identifies all individuals with appendicitis) and its specificity (which documents how well the score excludes those without appendicitis). The sensitivities reported here are calculated from the number of individuals with and without appendicitis when using the low-probability cutoff. The specificities are calculated from the number of individuals with and without appendicitis when using the high-probability cutoff. The measure of a score’s utility can also be assessed by the proportion of patients who remain in the indeterminate group—that is, the group that requires additional resources and imaging for diagnosis. All patients in indeterminate groups should be further evaluated either through diagnostic imaging or by observation, at the discretion of the treating clinician.

Table 39.2 presents some common appendicitis scoring systems.51-53 Table 39.3 presents cutoff values, sensitivities and specificities, and size of the indeterminate group for these same scoring systems.51-57 Please note that the scoring systems have been applied in many more settings than can reasonably be presented here and that the accuracy of the scoring systems may vary significantly by study. In particular, the Alvarado score, developed in 1986, has been studied extensively.

Sensitivities and specificities vary among studies that apply the same scoring system. Confounding variables include differences in patient age (in some pediatric studies, for example, children younger than 4 years are not included because the historical symptoms cannot be scored), differences in inclusion criteria (e.g., excluding patients with pain for more than 7 days), or differences in the prevailing rate of appendicitis in the study cohort (ranging from 20% to 80%). It is important to understand the demographics of your own patient population when applying these scoring systems.

NPV, Negative predictive value.
the appendix is located near the urinary tract. No upper limit of urinary WBC or RBC counts has been defined for appendicitis.

**IMAGING**

**Plain Radiographs**

Plain abdominal radiography is not indicated for the evaluation of potential appendicitis. Barium-enhanced imaging (via oral or rectal administration) demonstrates equally poor sensitivity because of nonfilling of the appendix and therefore has no role in the diagnosis of acute appendicitis. Plain radiography should be performed only to exclude suspected pneumoperitoneum, bowel obstruction, or foreign body.

**Helical Computed Tomography**

High-resolution helical CT is the diagnostic test of choice for suspected appendicitis (Fig. 39.1). CT findings in appendicitis include an appendiceal diameter greater than 7 to 10 mm, wall enhancement, wall thickening greater than 3 mm, and periappendiceal fat stranding.23,24 The reported sensitivity and specificity of helical CT for appendicitis in adults range between 91% and 96% and 90% and 95%, respectively.25-28

The use of CT as a diagnostic tool for suspected appendicitis has grown explosively in recent years, with adult imaging rates in the United States reported to be greater than 90%.29-31 CT imaging is correlated with a significant decrease in the negative appendectomy rate to less than 9%.29,32,33 The highest benefit of CT in reducing the negative appendectomy rate is appreciated in adult women.30,31 In the elderly, who often have atypical symptoms, the use of helical CT aids in early diagnosis and has reduced the rate of perforated appendicitis from 72% to 51%.9

Intravenous, rectal, or oral administration of a contrast agent to enhance CT imaging in patients with suspicion of appendicitis is controversial. Variations in patient population, contrast protocol, scanner resolution, and radiation dosing all contribute to reported diagnostic accuracy. Contrast agent administered enterally or intravenously enhances the appendiceal wall, lumen, and periappendiceal fat, thereby improving visualization of adjacent intraperitoneal organs. An intravenously administered contrast agent can provide valuable information in patients with little visceral fat but may cause allergic reactions or exacerbate renal insufficiency.34 An enterally administered contrast agent is particularly useful in the identification of perforation, but oral administration of a contrast agent may exacerbate nausea, and 1 to 2 hours is required for the contrast agent to traverse the gut before imaging. Newer-generation multislice CT systems have improved image resolution, even without contrast enhancement. Judicious use of non–contrast-enhanced protocols may reduce diagnostic delays and avoid potential contrast agent–related morbidity.35-37

Radiation exposure may be limited by using a focused appendiceal (right lower quadrant) CT study. Such protocols may be desirable for children and pregnant women, in whom large radiation exposure is a concern, but other intraabdominal disease may be missed.

In children, the sensitivity of helical CT for appendicitis with contrast enhancement is 92% to 100% and the specificity is 87% to 100%.7,28,36 The relative paucity of intraabdominal fat in children decreases the visualization of periappendiceal inflammatory changes, and contrast-enhanced protocols should be used to maximize diagnostic yield.

**Ultrasonography**

Graded compression ultrasonography is conducted by applying pressure at and around the point of maximum abdominal tenderness. Ultrasonographic findings highly associated with appendicitis include an enlarged, tender appendix greater than 6 mm in diameter with enhancing (hyperechoic) surrounding fat.24 Other signs include an inability to compress the appendix, the presence of periappendiceal fluid, and hypervascularity (Fig. 39.2). Formal ultrasonography for appendicitis has demonstrated sensitivities of 78% to 87% and specificities of 81% to 93% in nongravid adults.23-28 Accuracy is reduced by a thick abdominal wall and intestinal tract; consequently, ultrasonography is best used in thin patients and in children. It is the initial imaging test of choice in pregnant women and children, in whom one wishes to avoid radiation exposure. Ultrasonography is of added benefit when lower abdominal pain may be of pelvic etiology in women of childbearing age.

In children, the sensitivity and specificity of ultrasonography for the diagnosis of appendicitis range from 78% to 100% and 88% to 98%, respectively.26,36

![Fig. 39.1 Plain abdominal radiography and computed tomography demonstrating appendicitis. A. The plain film shows an appendiceal fecalith (arrow) overlying the iliac crest. Computed tomography with oral contrast enhancement demonstrates an enlarged, fluid-filled appendix (arrow, B) and a fecalith with periappendiceal inflammation (arrow, C).](image-url)
Emergency sonography is compelling because it does not require radiation exposure and can be performed rapidly at the bedside by the clinician. However, large variations in sensitivity (65% to 96%), probably related to operator experience, reduce its current utility as a reliable diagnostic tool.\(^{38,39}\)

**Combined Ultrasound and Computed Tomography Protocols**

CT is more sensitive and specific for the diagnosis of appendicitis than ultrasound is in both adult and pediatric populations, and the accuracy of ultrasound is highly operator dependent. However, concern regarding radiation exposure—especially in children—has led to the implementation of protocols involving ultrasound and then CT in which only patients with negative or nondiagnostic findings on ultrasound undergo CT. This serial diagnostic approach has been applied to both adults and children, with sensitivities and specificities ranging from 94% to 100% and 86% to 94%, respectively.\(^{7,40-42}\) Concerns that delays in definitive therapy associated with serial imaging protocols could cause an increase in the rate of perforated appendicitis have not been validated.

**Magnetic Resonance Imaging**

Findings on magnetic resonance imaging (MRI) in patients with appendicitis consist of a thickened appendiceal wall, a dilated lumen filled with high-intensity material, and periappendiceal enhancement on T2-weighted images. The utility of MRI in diagnosing appendicitis is curtailed by its limited availability, higher cost, and longer image acquisition time. MRI may be appropriate in patients in whom radiation exposure is contraindicated and ultrasonography is nondiagnostic.\(^{43,44}\)

**TREATMENT**

Early surgical consultation should be obtained whenever appendicitis is suspected (Box 39.3). Delays in surgery raise the risk for appendiceal perforation, peritonitis, and sepsis. Children, pregnant women, and elderly patients with abdominal pain have especially atypical manifestation and are at higher risk for perforation. Surgical consultation should not be delayed for testing, and testing should be undertaken only when the clinical diagnosis is in question.

Intravenous administration of isotonic crystalloid should be initiated as indicated, particularly if prolonged vomiting, anorexia, or fever has been reported. In anticipation of surgery, the patient should be advised not to eat or drink. Control of pain and nausea is both medically rational and humane. Narcotic administration has not been shown to affect the sensitivity of the physical examination in either adults or children or delay the time to diagnostic decision making, although adequately powered studies in children are lacking.\(^{45-47}\) Analgesia with morphine sulfate, hydromorphone, or fentanyl is appropriate. An antiemetic, such as ondansetron, promethazine, prochlorperazine, or metoclopramide, may also be required.

Prophylactic administration of antibiotics has been shown to reduce perioperative infection rates in both simple (nonperforated) and complicated (perforated or gangrenous) appendicitis.\(^{49,50}\) Their administration should be timed in consultation with the surgeon so that high antibiotic tissue levels coincide with the surgical procedure. The antibiotics should be effective against both skin flora and common appendiceal pathogens, including *Escherichia coli*, *Klebsiella*, *Proteus*, and *Bacteroides* species (Table 39.4).

**DISPOSITION**

Patients in whom the findings are a concern despite normal laboratory and imaging results should be admitted for observation and serial abdominal examinations (Box 39.4). Patients with undifferentiated abdominal pain, low risk for

---

**Fig. 39.2** Transabdominal ultrasonography in a 37-year-old woman with pelvic pain. A, Cross-sectional view of a dilated appendix (large arrow) with periappendiceal fluid (small arrow). B, Compression yields minimal change in appendiceal diameter and causes significant pain. C, A longitudinal view of the appendix (small arrows) and its origin at the cecum (large arrows).
appendicitis, and negative diagnostic evaluation results may be considered for discharge if their clinical symptoms improve and they are able to tolerate oral fluids. Arrangements should be made for close follow-up for such patients, who should be given specific instructions to return to the ED if their symptoms worsen. Antibiotics should not be prescribed for discharged patients with undifferentiated abdominal pain. Narcotic analgesics may mask disease progression and are not recommended.

**TIPS AND TRICKS**

If a patient is discharged with the diagnosis of acute abdominal pain, ensure that the plan for that patient is clear and specific. Ask the patient or caregiver to repeat the explained plan. Be sure to include the time and place of the repeat abdominal examination.

Check that the β-human chorionic gonadotropin level is determined in all female patients of childbearing age.

Be certain that the imaging study demonstrates a normal appendix to exclude the diagnosis. Caution should be used when attributing pain to an ovarian cyst or uterine fibroid discovered on ultrasound.

**DOCUMENTATION**

Include the following elements in your documentation:

- Initial physical examination and serial abdominal examinations
- Differential diagnosis of the patient’s abdominal pain
- Discussions with consultants, patient, and family members

If a patient with unexplained abdominal pain is discharged, explain why you concluded that the patient did not have acute appendicitis. Include laboratory results, imaging studies, serial examinations, and consultations. Document in the discharge instructions when the patient with unexplained abdominal pain should undergo a repeat abdominal evaluation: 8, 12, 24, or 36 hours.

Bowel obstructions develop from mechanical blockage of normal intestinal transit. Blockages may result from intraluminal matter (e.g., foreign bodies), intramural wall thickening (tumors, hernia, inflammation), or extraluminal compression (hernias, masses, adhesions). Bowel proximal to the obstruction progressively dilates, which leads to pain, obstruction (inability to pass flatus), and vomiting. Dehydration and electrolyte abnormalities ensue. As the bowel wall becomes edematous, increasing pressure causes collapse of the capillary bed and subsequent tissue ischemia, a condition known as strangulation. Strangulation may lead to bowel wall necrosis, perforation, peritonitis, sepsis, and death. Patients with small bowel obstruction have a 5% to 42% incidence of strangulation, which carries a mortality of 20% to 37%.

Obstruction can be partial, with some intestinal contents allowed to progress through the area of narrowing, or complete. A patient with complete obstruction has a low likelihood of spontaneous resolution and a high likelihood of bowel strangulation, whereas a patient with partial obstruction can typically be managed nonoperatively because of the lower risk for bowel strangulation. The central dilemma in caring for patients with small bowel obstruction is to identify those at risk for strangulation to ensure timely surgical intervention.

PATHOPHYSIOLOGY

Bowel obstructions can be divided into simple obstructions (bowel occlusion at one location with an intact blood supply) and closed-loop obstruction (occluded loop of bowel at two adjacent points, which may or may not involve a vascular pedicle). Closed-loop obstructions are most commonly caused by entrapment of bowel in a hernia (incarceration) or, less commonly, by volvulus. Closed-loop bowel obstructions have a higher likelihood of concomitant vascular compromise and strangulation, thus warranting a more aggressive management approach.

Large bowel obstructions are at increased risk for perforation if a closed-loop obstruction is present or if the ileocecal valve is functional (preventing proximal decompression into the small bowel). The most likely sites of perforation are at the cecum (especially if the diameter is larger than 10 cm) or at the site of a primary tumor.

Volvulus, or axial twisting of the bowel, represents a special category of closed-loop obstruction. Volvulus occurs most commonly at either the cecum or the sigmoid colon and much less frequently at the transverse colon, small bowel, or stomach. Sigmoid volvulus, which is responsible for 50% to 75% of all cases of colonic volvulus, is more common in elderly and institutionalized patients. Cecal volvulus is found in younger patients, who may have an anatomic predisposition because of abnormal fixation of the right colon.

CLINICAL PRESENTATION

Bowel obstructions are manifested as colicky abdominal pain that precedes the onset of nausea and vomiting, abdominal distention, constipation, and obstruction. Proximal small bowel obstructions tend to have minimal distention and an
early onset of intractable vomiting because the bowel proximal to the obstruction has minimal capacity to distend. Conversely, distal small bowel obstructions are characterized by abdominal distention, colicky abdominal pain, and obstipation before the onset of vomiting. Large bowel obstruction may be preceded by changes in stool caliber and progressive abdominal distention when it is caused by a slow-growing tumor, or it may be sudden in onset in the setting of volvulus.

Physical examination may detect signs of volume depletion, tachycardia, and hypotension. Fever suggests strangulation and perforation. The abdomen is variably distended and tympanitic, depending on the level of obstruction. Scars from previous surgery can provide valuable clues to the cause of the obstruction. Bowel sounds tend toward high-pitched rushes of “tinkling” borborygmi; a silent abdomen is an ominous sign of perforation and peritonitis. Tenderness may be present, but localized tenderness and peritoneal signs indicate perforation. The examination should include a search for hernias.

A digital rectal examination should be performed to exclude stool impaction in the elderly. Occult blood may be detected in cases of strangulated obstruction, intussusception, or an obstructing mass. A rectal mass may be identified as the cause of large bowel obstruction.

**DIFFERENTIAL DIAGNOSIS**

Many abdominal disorders may cause a functional ileus that can be mistaken clinically for bowel obstruction.

Potential causes of mechanical small or large bowel obstruction are summarized in Box 40.1.

**DIAGNOSTIC TESTING**

**LABORATORY TESTING**

Laboratory abnormalities are not diagnostic of bowel obstruction but instead may indicate complications of obstruction. A complete blood count may demonstrate leukocytosis with a left shift in a patient with strangulation; serum chemistry evaluations may show dehydration, hypokalemia, and acid-base disturbances. The serum lactate concentration can be elevated in the setting of strangulation, but its measurement is neither sensitive nor specific.²

**RADIOGRAPHS**

Plain supine and upright radiographs of the abdomen are the most commonly ordered initial diagnostic study for bowel obstruction because of their widespread availability and the low cost of radiographic evaluation (Fig. 40.1).

Small bowel obstruction appears on radiographs as air-fluid levels and dilated loops of bowel. Air in the distal part of the colon and rectum implies early or partial small bowel obstruction. As the obstruction progresses, small bowel dilation and air-fluid levels become more prominent, and the distal end of the bowel decompresses and collapses.

Ileus is distinguished from mechanical obstruction by the presence of air-fluid levels at uniform height across an upright image of the abdomen; with obstruction, air-fluid levels are classically found at variable heights.

---

**Fig. 40.1**  Supine radiograph showing very distended small bowel identified by its central position, multiple loops, and valvulae conniventes. (From Adam A, Dixon AK, Grainger & Allison’s diagnostic radiology. 5th ed. Philadelphia: Churchill Livingstone; 2008.)

Plain radiography is less useful for closed-loop obstructions, which are detected only by the subtle finding of a paucity of intestinal gas in the region of an often fluid-filled closed loop.

Sigmoid volvulus is characterized by a massively distended loop of large bowel arising out of the pelvis, sometimes
Sigmoid volvulus.

Researchers have used combinations of discharge diagnosis, in diagnosing obstruction are limited by their methodology. In addition, a contrast agent enema improves the sensitivity and specificity for characterizing closed-loop obstruction; (4) to demonstrate signs of strangulation; and (5) to identify alternative causes of acute abdominal pain when obstruction is not present.

Computer tomography (CT) has supplanted the emergency department (ED) use of contrast-enhanced radiography to confirm suspected bowel obstruction when initial plain radiographs are nondiagnostic (typically in cases of low-grade or intermittent obstruction).

**COMPUTED TOMOGRAPHY**

CT of the abdomen is commonly used for the diagnosis of bowel obstruction (1) to confirm a clinically suspected obstruction not identified on a plain radiograph; (2) to determine the level, severity, and cause of the obstruction; (3) to characterize a closed-loop obstruction; (4) to demonstrate signs of strangulation; and (5) to identify alternative causes of acute abdominal pain when obstruction is not present.

CT has a sensitivity of 64% to 100% and a specificity of 71% to 100% for the diagnosis of bowel obstruction. Signs of small bowel obstruction on CT consist of small bowel dilation to a caliber of 2.5 cm or greater with a distinct transition zone and a collapsed distal bowel lumen. The “small bowel feces sign”—the presence of intraluminal particulate material in dilated small bowel—can be helpful in confirming the diagnosis of small bowel obstruction. CT correctly identifies the cause of obstruction in 73% to 95% of patients.

A completely fluid-filled closed-loop obstruction is more easily diagnosed with CT than with plain radiography. Characteristics of closed-loop obstruction include a C- or U-shaped configuration of the dilated loops, a radial distribution of the dilated loops toward the site of obstruction, a radial distribution and engorged mesenteric vessels toward the site of obstruction (the “beak and whirl” sign), and the presence of two collapsed bowel lumens adjacent to the site of obstruction.

Intravenous contrast-enhanced CT has a sensitivity for the diagnosis of strangulation of 56% to 85% and a specificity exceeding 90%. Strangulation is suggested by a characteristic configuration of the obstructed loop, bowel wall thickening and reduced contrast enhancement, mesenteric vascular changes, gas in the bowel wall, and the presence of free peritoneal fluid. Combinations of clinical, laboratory, and radiographic features have been used in an attempt to identify patients with strangulation who need urgent surgery. One study suggested that the presence of any three of six variables (duration of pain longer than 4 days, abdominal guarding, C-reactive protein level higher than 75 mg/L, white blood cell count greater than 10,000/mm³, presence of more than 500 mL of intraabdominal fluid on CT, or reduced wall contrast enhancement on CT) had a sensitivity of 68% for resection of small bowel. Another study found that the presence of two of four clinical criteria (tachycardia, leukocytosis, fever, and tenderness) increased the specificity of the CT criteria.
CT enteroclysis (delivery of contrast agent to the small bowel via a tube so that it bypasses the pylorus) combines the anatomic information provided by CT with the intraluminal detail of enteroclysis. Although this technique is more labor-intensive because of the need to intubate the small bowel, it may play a role in the future evaluation of small bowel obstruction.\textsuperscript{13} CT enteroclysis is a useful test for confirming the diagnosis of superior mesenteric artery syndrome, a rare cause of proximal small bowel obstruction that occurs after rapid weight loss.

Orally administered WSCA can help distinguish partial small bowel obstruction from complete obstruction. Two separate metaanalyses have shown that identification of oral contrast agent in the colon 4 to 24 hours after administration predicts the success of conservative management with a pooled positive likelihood ratio of 25 to 40 and that the absence of contrast agent predicts failure of conservative therapy with a pooled negative likelihood ratio of 0.03 to 0.04.\textsuperscript{16,17}

**TREATMENT**

**CONSERVATIVE MANAGEMENT OF SMALL BOWEL OBSTRUCTION**

“Don’t let the sun set on a bowel obstruction.” This adage has guided surgeons since the advent of operative therapy for this condition inasmuch as clinical and radiographic predictors of strangulation were poor before the advent of CT. In the modern era, however, nearly half of all patients with acute small bowel obstruction improve with conservative therapy.\textsuperscript{18} The mainstay of nonoperative treatment is gastric decompression via nasogastric suctioning. The nasogastric tube is easy to insert, requires no fluoroscopic guidance to place, and reduces the risk for aspiration pneumonia by effectively relieving the gastric distention. Nasointestinal (long) tubes that cross the pylorus are not recommended for ED use.

Small bowel obstructions caused by postoperative adhesions in the first 30 days after laparotomy complicate up to 10% of procedures. These early adhesions represent inflammatory reactions, unlike the fibrous adhesions that develop later in the postoperative course. Obstructions occurring in the early postlaparotomy period can usually be managed nonoperatively because more than 85% resolve spontaneously.\textsuperscript{19} Conversely, early postlaparoscopic small bowel obstructions generally require surgery because they are typically caused by herniation of bowel through the peritoneal defect made by the trochar.\textsuperscript{20}

Oral contrast agents have been postulated to have a therapeutic role in resolving small bowel obstructions because WSCAs are hyperosmolar and draw water into the small bowel lumen while decreasing bowel wall edema, but studies have demonstrated conflicting results. A metaanalysis of four trials demonstrated no significant difference between WSCAs and placebo in successful nonoperative management of acute small bowel obstruction; however, hospital stay was shorter in patients given WSCAs than in patients receiving placebo.\textsuperscript{16}

**SURGICAL MANAGEMENT OF SMALL BOWEL OBSTRUCTION**

Surgical excision of an obstructive lesion and assessment of bowel viability are mandated for all cases of suspected bowel strangulation. Viability is assessed by visual inspection of the decompressed bowel during surgery; in questionable cases, fluorescein injection and subsequent fluorescence of the intestines confirm viability. Complete small bowel obstructions and closed-loop obstructions pose higher risks for strangulation and are therefore managed more aggressively with surgical intervention. A trial of nasogastric decompression is reasonable for partial small bowel obstructions.

Laparoscopic treatment of small bowel obstruction appears to be appropriate for carefully selected patients.\textsuperscript{21} The most significant complication of laparoscopy is iatrogenic perforation of bowel, which occurs in 1% to 16% of patients. Between 8% and 40% of cases initially planned as laparoscopic procedures are converted to laparotomy intraoperatively. Prospective studies are needed to further compare the risks and benefits of laparoscopic and open surgery for acute small bowel obstruction (Fig. 40.3).

**MANAGEMENT OF LARGE BOWEL OBSTRUCTION**

Large bowel obstruction can be divided into four types according to treatment options: mechanical obstruction as a result of cancer, sigmoid volvulus, cecal volvulus, and pseudoobstruction. Mechanical large bowel obstruction is treated surgically, with resection and primary anastomosis in most cases of right and transverse colon carcinoma. For carcinoma of the left colon, either initial decompression followed by staged resection or immediate resection (with or without primary anastomosis) is performed. Palliative treatment of obstruction secondary to disseminated or recurrent carcinoma includes creation of a colostomy (or ileostomy for right-sided masses) proximal to the obstruction, corticosteroids, placement of a self-expanding stent, and chemotherapy.

Sigmoid volvulus is initially treated by nonoperative decompression, followed by elective surgery to prevent recurrence after colonoscopy excludes the possibility of carcinoma.
Decompression can be performed via rigid or flexible endoscopic detorsion of the twisted segment. Endoscopy is contraindicated in patients with suspected intestinal necrosis. A rectal tube may be left in place before surgery to facilitate further decompression and prevent recurrence during hospitalization.

Cecal volvulus is managed surgically, with most surgeons choosing a right colectomy as definitive therapy. Cecopexy, or manual detorsion and subsequent correction of the underlying hypermobile right colon, is associated with a high rate of recurrent volvulus.

Pseudoobstruction can initially be managed nonsurgically with a combination of decompression, colonoscopy, and promotility agents, including neostigmine. Medications that slow colonic motility should be discontinued, and suspected infectious causes should be treated appropriately. Surgical management is indicated when conservative therapy fails or in cases of suspected colonic ischemia, perforation, or sepsis. Because of the large number of potential causes of pseudoobstruction, inpatient management with surgical and gastroenterologic consultation is recommended.

**DISPOSITION**

Surgical consultation is indicated for all patients with partial or complete bowel obstruction. Such patients require hospital admission for resuscitation, decompression, serial abdominal examination, and possibly operative therapy.

REFERENCES

KEY POINTS

- Structures proximal to the dentate line are insensitive, but tissue external to this boundary can be painful when damaged by trauma, infection, or inflammation.
- An anoscope should be used to directly visualize the internal anatomy if abnormalities are suspected.
- Internal hemorrhoids cannot be distinguished from normal rectal tissue by digital rectal examination. Anoscopy is required to visualize suspected internal hemorrhoids.
- Thrombosed external hemorrhoids are treated with an elliptical incision rather than a linear incision and drainage.
- Fissures that are not properly treated may become chronic and develop the classic triad consisting of sentinel pile, deep ulcer, and enlarged anal papillae.
- Pain that subsides between bowel movements is classic for anal fissures.
- Any patient with suspected rectal perforation because of a foreign body (insertion or removal) should undergo proctosigmoidoscopy performed by a gastroenterologist or colorectal surgeon before discharge.

PERSPECTIVE

The anorectum marks the end of the digestive tract as it transitions from the endodermal tissues of the colon and intestine to the ectodermal tissues of the skin (Fig. 41.1). The rectum is the portion of the digestive tract that extends distally from the rectosigmoid junction at approximately the level of the S3 sacral vertebral body to the dentate line. At the dentate line, the endodermal tissue transitions to ectodermal tissue. The first 1 to 2 cm is considered the anal canal. This tissue, the anoderm, is squamous in origin but contains no hair follicles or sweat glands. At the anal verge, this tissue transforms to more normal external skin marked by hair follicles, apocrine glands, and subcutaneous tissue.

Just proximal to the dentate line, the tissue of the rectum takes on a pleated appearance and forms the rectal ampulla. These pleats create multiple crypts and the anal valves with their insertion at the dentate line. Proximal to the crypts are the columns of Morgagni, where the epithelium of the anoderm transitions to that of the rectum.

Because of the varying embryonic origins of the anorectal region, the vasculature and innervation demonstrate distinct areas of function. The superior, middle, and inferior hemorrhoidal arteries supply blood to the anorectum; they arise, respectively, from the inferior mesenteric, internal iliac, and internal pudendal arteries. Likewise, venous drainage of the rectum is divided between the superior hemorrhoidal vein (which drains into the portal system) and the inferior hemorrhoidal vein (which drains into the caval system).

Sensory perception of the rectum is supplied by the pudendal nerve, which arises from pelvic branches of the S3 and S4 nerve roots. Structures proximal to the dentate line are insensitive, whereas tissue distal to this boundary can be painful when damaged by trauma, infection, or inflammation.

Fecal continence is maintained by motor innervation that arises from the S2 to S4 nerve roots. Defecation is the result of concomitant parasympathetic and sympathetic simulation, as well as voluntary contraction of the abdominal muscles.

EXAMINATION

To examine the anorectum, the emergency physician (EP) places the patient in the lateral decubitus position (Sims position) or a knee-to-chest position on the examination table (Fig. 41.2). The anorectal skin, hygiene, and any anatomic abnormalities are inspected. The EP has the patient bear down (Valsalva maneuver) to accentuate any prolapse of the rectum or internal hemorrhoids. The skin of the anorectum is spread to identify fissures that may be hidden in the folds. A 360-degree digital rectal examination is performed, with note being made of the prostate in males and the cervix in females. The sample of stool on the withdrawn glove is assessed for gross or occult blood. If abnormalities are suspected, an anoscope is used to directly visualize the internal anatomy.

ANORECTAL ABSCESS

PATHOPHYSIOLOGY

Anorectal abscesses are caused primarily by infection of obstructed anal glands, ducts, and crypts. Abscesses are polymicrobial and involve both anaerobic and aerobic bacteria. Other causes of anorectal abscess are immunosuppression, atypical infection (e.g., tuberculosis, actinomycosis, lymphogranuloma venereum), inflammatory bowel disease (Crohn disease), trauma (e.g., foreign body), surgery (e.g., anorectal, genitourinary, and gynecologic procedures), malignancy (e.g., rectal carcinoma, leukemia, lymphoma), radiation, and anal fissures. Anorectal abscesses are classified according to location. The four main types are perianal (most common), ischiorectal, intersphincteric, and suprapellevator (least common) (Fig. 41.3).

PRESENTING SIGNS AND SYMPTOMS

General complaints in patients with anal abscesses are pain, swelling, and occasionally fever. Signs and symptoms of a perianal abscess are a tender, erythematous, fluctuant mass at the anal verge and pain that worsens with sitting or defecating. The patient is usually afebrile. If large, an ischiorectal abscess may be manifested as a lateral perianal swelling. The patient has severe buttock pain but typically little to no cutaneous findings. Fever and leukocytosis are also present.
DIAGNOSTIC TESTING AND EXAMINATION

- Classic history and physical examination findings
- Abdominal examination to evaluate for intraabdominal involvement
- Perianal examination to evaluate for perianal abscess and cellulitis
- Rectal examination to evaluate for deeper abscesses
- Vaginal examination to evaluate for deeper abscesses
- Bedside glucose measurement to evaluate for diabetes mellitus
- Abdominal and pelvic computed tomography (CT) or ultrasonography to identify deep abscesses when suspected

TREATMENT

PERIANAL ABSCESS

Patients who do not have a complicating disorder and whose perianal abscess (Fig. 41.4) measures 10 cm or smaller may
CRYPTITIS

**PATHOPHYSIOLOGY**

The anal crypts are small pockets of epithelium located between the anal papillae at the proximal end of the anal canal (the mucocutaneous junction). These crypts have tiny glands that secrete a small drop of mucus as the sphincter muscles contract to ease the passage of stool. Cryptitis occurs when these crypts become inflamed and the mucosal lining of their roofs becomes denuded. Possible causes of cryptitis are as follows:

- Repeated watery stools that can cause trauma or deposits in the crypts
- Direct trauma from large, hard stools
- Inflammation from adjacent structures
- External sources of infection, such as parasites or foreign bodies

If left untreated, cryptitis can lead to perirectal abscess, anal fissure, or anal fistula.

**PRESENTING SIGNS AND SYMPTOMS**

The signs and symptoms of cryptitis are anal pain (rectalgia), which is described as burning or dull in nature and exacerbated with bowel movements, as well as anal spasm, pruritus, and occasionally bleeding.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis for cryptitis includes hemorrhoids, anal fissure, anorectal abscess, and proctitis.

**DIAGNOSTIC TESTING AND EXAMINATION**

- Palpation of hypertrophied (indurated) papillae adjacent to the crypt
- Classic “pearl of pus” beading from the crypt at the dentate line on anoscopy

**TREATMENT**

Treatment of cryptitis consists of bulk laxatives to promote well-formed stools and decrease trauma, as well as warm sitz baths. Patients with advanced disease should receive outpatient surgical referral for excision of the gland.

**ANAL FISSURE**

**PATHOPHYSIOLOGY**

An anal fissure, also called fissure in ano, is a superficial linear tear of the anoderm that begins at or just below the dentate line and extends distally toward the anal verge. Anal fissures are the most common cause of painful rectal bleeding; they are also the most common cause of rectal bleeding in infants.

Ninety-nine percent of fissures in men and 90% of fissures in women are in a posterior midline location. Posterior midline anal fissures are typically caused by the passage of large, hard...
stool through a tight anus. The posterior midline is affected most because of weaker skeletal muscle and the acute angle of the rectum on the anus posteriorly.

Anterior midline fissures are most common in postpartum women. Anal fissures in other areas can be caused by rectal anal intercourse or insertion of foreign bodies or may be manifestations of conditions such as Crohn disease, cancer, tuberculosis, HIV infection, and syphilis.

Fissures that are not properly treated may become chronic and develop the classic triad consisting of sentinel pile, deep ulcer, and enlarged anal papillae. The ulcerating fissure causes edema and irritation of the surrounding tissue. Proximally, the result is hypertrophied papillae. Distally, the result is the formation of sentinel pile—fibrotic tissue that may be confused with an external hemorrhoid. The sentinel pile may eventually develop into a skin tag.

**PRESENTING SIGNS AND SYMPTOMS**

In infants, anal fissures are signified by small amounts of bright red blood on the stool or diaper. Children with anal fissures have painful defecation and “constipation” because of refusal to defecate because of pain.

Adults describe a sharp, cutting, or burning pain with defecation that can persist as a nagging, dull pain for several hours but usually subsides between bowel movements. A small amount of bright red blood may be noted on the stool or toilet paper. Sphincter spasm may also occur and cause further pain.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of anal fissure includes hemorrhoids, proctitis, cryptitis, perianal abscess, and primary syphilis (chancre).

**DIAGNOSTIC TESTING AND EXAMINATION**

Diagnosis of an anal fissure must be made by physical examination, which should be done very carefully to avoid further spasm and pain. Application of a topical anesthetic such as lidocaine jelly may be necessary to facilitate the examination. Gentle retraction of the buttocks and perianal skin with the lidocaine jelly may be necessary to facilitate the examination. Proximally, the result is hypertrophied papillae. Distally, the result is the formation of sentinel pile—fibrotic tissue that may be confused with an external hemorrhoid. The sentinel pile may eventually develop into a skin tag.

Because of the severe pain and spasm, the patient may not be able to tolerate a digital rectal examination. If such an examination is performed, the surrounding hypertrophic papillae may be palpated.

If the fissure is not located in the midline, the differential diagnosis and consequent testing must be expanded to include more serious conditions such as cancer, HIV disease, Crohn disease, sexually transmitted diseases, and tuberculosis.

**TREATMENT**

Medical treatments that are most common and most effective for anal fissures are as follows:

- Warm sitz baths for 15 minutes three times per day
- A high-fiber diet
- Oral analgesics (narcotics increase constipation and should thus be avoided)

Chronic fissures for which medical treatment fails are often repaired successfully through a lateral internal sphincterotomy, which is performed by a surgeon. Patients with nonmidline fissures should be referred for further diagnostic testing, including ulcer biopsy and anal cultures.

**ANAL FISTULA**

**PATHOPHYSIOLOGY**

Anal fistula, also called fistula in ano, is considered a chronic variant of a poorly healed anorectal abscess. Fistulas are tracts between the anal canal (or rectum) and the skin that are lined with epithelial or granulation tissue. Although anal fistulas typically arise from an anorectal abscess, they can also be associated with inflammatory bowel disease, malignancies, infection (sexually transmitted diseases, actinomycosis, tuberculosis, and diverticulitis), anal fissures, or foreign bodies.

**PRESENTING SIGNS AND SYMPTOMS**

The signs and symptoms of anal fistulas are a blood-tinged, malodorous discharge and rectal pain that improves with an increased discharge. An abscess may be located at the opening of the fistula. The fistula can be palpated as a cord leading to the sphincter.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of anal fistula consists of abscess, hemorrhoid, anal fissure, and gonococcal proctitis.

**DIAGNOSTIC TESTING AND EXAMINATION**

- Anal and rectal examinations with classic findings
- Abdominal and pelvic CT demonstration of a fistula tract
- Transanal ultrasonography (with or without hydrogen peroxide injected into the tract)

**TREATMENT**

Treatment of anal fistulas consists of surgical excision to eliminate the fistula, prevent recurrent disease, and preserve sphincter function. Stable patients may be referred for urgent outpatient surgical consultation.

**ANORECTAL FOREIGN BODIES**

**PATHOPHYSIOLOGY**

The structure of the rectum and distal end of the colon predisposes a foreign body to migrate cephalad after insertion. A delay in evaluation may also allow the development of...
edema, which further complicates removal of a foreign body. Foreign bodies with smooth contours and a diameter near that of the rectum or colon may become “vacuum-locked” in place, with attempts at removal causing collapse of the rectum or colon distal to the object.

**PRESENTING SIGNS AND SYMPTOMS**

Although anorectal foreign bodies are often the subject of humor and medical lore, ED management of an anorectal foreign body is actually quite rare. Because of the social stigma involved, patients are reluctant to come to the ED and are often not forthcoming about their actual complaint. The patient has frequently attempted to remove the foreign body before seeking medical attention, thereby potentially causing further damage or complicating removal.

Although the majority of patients give an accurate history, some have vague complaints of abdominal pain or an unlikely story about how the object became lodged in the rectum. In the ED, every effort must be made to ascertain the type, shape, number, and composition of a retained foreign body, as well as how long it has been in the anorectum, before removing it.

**RED FLAGS**

<table>
<thead>
<tr>
<th>Foreign Bodies</th>
<th>Type: glass, food, metallic, sharp</th>
</tr>
</thead>
<tbody>
<tr>
<td>Shape</td>
<td></td>
</tr>
<tr>
<td>Number of objects present</td>
<td></td>
</tr>
<tr>
<td>Time of insertion (delays in treatment promote edema)</td>
<td></td>
</tr>
</tbody>
</table>

**DIFFERENTIAL DIAGNOSIS**

Objects lodged in the anorectum may have been self-inserted, inserted as a result of sexual assault, iatrogenically inserted (e.g., rectal thermometer), or swallowed.

**DIAGNOSTIC TESTING AND EXAMINATION**

The shape, composition, surface, contour, and orientation of a foreign body influence the ultimate method of removal. Most foreign bodies can be classified as low lying and therefore palpable in the rectal ampulla or as high lying, at or proximal to the rectosigmoid junction.

Examination and diagnostic testing should include the following:

- Thorough palpation of the abdomen (to identify masses, peritonitis)
- Flat and upright radiographs of the abdomen
- Digital rectal examination (if the object is not sharp by patient report and does not appear sharp on radiographs)

Anoscopy to visualize the foreign body should be considered.

**TREATMENT**

Treatment of an anorectal foreign body is based on the results of abdominal and rectal examination, as well as plain radiographs (Fig. 41.5). Patients with palpable, low-lying foreign bodies can undergo conscious sedation and local anesthesia for attempted removal in the ED. Patients with high-lying foreign bodies or risk for perforation should be managed operatively.

**FOLEY CATHETER REMOVAL OF ANORECTAL FOREIGN BODIES**

A Foley catheter can be used to break the suction caused by insertion of an object with a diameter similar to that of the colon or rectum; the procedure is as follows (Fig. 41.6):

1. Place the patient in the lithotomy position.
2. Pass one or more Foley catheters beyond the foreign body.
3. Insufflate air to break the suction.
4. Inflate the Foley balloons.
5. While grasping the foreign body and applying gentle traction with either hands or forceps, slowly remove the catheter or catheters with moderate pressure.
A patient who underwent successful removal of a low-lying foreign body may be discharged from the ED. For any patient with suspected rectal perforation, proctosigmoidoscopy should be performed by a gastroenterologist or colorectal surgeon before disposition.

HEMORRHOIDS

PATHOPHYSIOLOGY

The hemorrhoidal plexuses provide a vascular cushion to the area surrounding the anus. The hemorrhoidal vessels are one of three layers of submucosal tissue that support the anal canal and aid in continence and defecation. As this tissue deteriorates and weakens, the hemorrhoidal veins may prolapse or may become engorged or thrombosed.

The internal hemorrhoidal veins are located above the dentate line. Their blood supply is derived from the superior hemorrhoidal plexus, and drainage is into the portal system by way of the superior rectal veins and the inferior mesenteric vein. They also communicate with the external hemorrhoidal veins. Internal hemorrhoids are covered by transitional or columnar epithelial mucosa without pain fibers. They are nearly always in the same positions: left lateral (9 o’clock), right posterolateral (5 o’clock), and right anterolateral (2 o’clock) (Fig. 41.7). They are classified into four categories according to severity (Table 41.1).

The external hemorrhoidal veins are located below the dentate line. Their blood supply is derived from the inferior hemorrhoidal plexus, with drainage into the iliac and pudendal venous systems. They are covered by anoderm (modified squamous epithelium) with sensory nerve endings that contain pain receptors.

PRESENTING SIGNS AND SYMPTOMS

The most common symptom of hemorrhoids is painless bleeding with defecation (blood on stool or toilet paper). If the hemorrhoid is thrombosed, strangulated, or prolapsed, pain with defecation also occurs. The lesion is detected as a curvilinear mass at the anus.

Prolapsed hemorrhoids also cause discharge of mucus and pruritus ani. A thrombosed external hemorrhoid appears as a dark blue, firm, tender mass distal to the anal verge. A prolapsed, strangulated internal hemorrhoid appears as a purplish tender mass covered by mucosa and emerging from the anal verge. A strangulated internal hemorrhoid is often associated with a thrombosed external hemorrhoid.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for hemorrhoids consists of anal fissure, rectal prolapse, perianal condyloma, abscess, fistula, rectal varices, tumors, and manifestations of inflammatory bowel disease.

DIAGNOSTIC TESTING AND EXAMINATION

The diagnostic criteria for hemorrhoids are as follows:

- Prolapse of hemorrhoids is noted on rectal examination when the patient bears down.
- Internal hemorrhoids are not palpable, so anoscopy is required to visualize them.

TREATMENT

As a rule, most hemorrhoids should be treated conservatively, as follows:

- Warm sitz baths for 15 minutes three times per day
- Increase in dietary fiber
- Stool softeners and bulk laxatives (those causing liquid stool, which could lead to cryptitis, should be avoided)
- 0.2% topical nitroglycerin ointment to treat pain by decreasing sphincter spasm
- Topical anesthetics and steroid creams, though controversial, provide anecdotal pain relief
- Judicious use of narcotics (stool softeners should also be used if narcotics are prescribed)

<table>
<thead>
<tr>
<th>SEVERITY (DEGREE)</th>
<th>FINDINGS</th>
</tr>
</thead>
<tbody>
<tr>
<td>First</td>
<td>No prolapse; painless bleeding</td>
</tr>
</tbody>
</table>
| Second            | Prolapse with straining and spontaneous reduction
                    | Mild discomfort and bleeding |
| Third             | Prolapse with straining, which requires manual reduction
                    | Some throbbing pain, itching, bleeding, and mucus discharge |
| Fourth            | Permanent prolapse that cannot be reduced
                    | Pain and bleeding common
                    | Potential for thrombosis and strangulation |

Fig. 41.7  Common positions of internal hemorrhoids.
Acutely thrombosed external hemorrhoids can be excised in the ED (Fig. 41.8). Rather than performing simple incision and drainage, the EP should excise the roof of the thrombosed hemorrhoid as an ellipse. Excision of thrombosed hemorrhoids should never be performed in the ED in children or in adults who are immunocompromised or pregnant, in patients receiving anticoagulation therapy, and in patients with portal hypertension.

**RED FLAG**

Excision of a nonthrombosed hemorrhoid should never be attempted.

**EXCISION PROCEDURE**

Thrombosed external hemorrhoids can be excised as follows (Fig. 41.9):

1. Put the patient in a prone or left lateral decubitus position.
2. If a single provider is performing the procedure without an assistant, tape the buttocks as shown in Figure 41.10.
3. With a 27-gauge needle, infiltrate bupivacaine with epinephrine into the overlying skin and the skin underneath the clot.
4. Make an elliptical incision in the overlying skin (distal to the anal verge).
5. Excise the clot or clots through this opening.
6. To control bleeding, place a small piece of gauze or absorbable gelatin sponge (Gelfoam) into this opening and cover with a pressure dressing.

The patient should remove the dressing in 6 hours, at the time of the first sitz bath.

**DISPOSITION**

Most patients with hemorrhoids can be discharged home. Immediate surgical consultation should be obtained for patients with strangulated fourth-degree internal hemorrhoids or bleeding hemorrhoids and severe anemia.

Patients with second-degree, third-degree, or nonstrangulated fourth-degree internal hemorrhoids should be referred to an outpatient surgeon for possible sclerotherapy, rubber band ligation, infrared coagulation, or excisional hemorrhoidectomy.

Patients who have undergone ED excision of thrombosed external hemorrhoids should be referred for follow-up with a surgeon.

**HIDRADENITIS SUPPURATIVA**

**PATHOPHYSIOLOGY**

Perianal hidradenitis suppurativa is a disease of the skin and subcutaneous tissue that arises from occlusion of the apocrine glands with keratin. It tends to be chronic, recurrent, and primarily localized to areas with the highest density of apocrine sweat glands (groin, axilla, and mammary regions). Sequelae include inflammation, infection, and eventual rupture of the gland with secondary cellulitis of the...
CHAPTER 41  ANORECTAL DISORDERS

BOX 41.1 Characteristics of Hidradenitis Suppurativa

Age at onset: puberty
Female-to-male ratio: 3:1
Associated conditions: acne, comedones, obesity, hirsutism
Sites affected (in descending order of frequency): axillary, inguinal, perianal and perineal, mammary and inframammary, buttock, pubic region, chest, scalp, retroauricular, eyelid

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of perianal hidradenitis suppurativa consists of carbuncles, lymphadenitis, infected sebaceous cysts, noninflamed cysts, other infectious processes (abscesses, fistulas), and Crohn disease.

TREATMENT

Medical treatment of perianal hidradenitis suppurativa consists of weight loss, smoking cessation (if applicable), and the use of antibiotics. Clindamycin, 300 mg twice daily, has been shown to be effective in suppression, but the disease often returns when use of the antibiotics ceases; topical clindamycin cream is similarly effective. Retinoids may also be tried. Acitretin, 25 mg daily, decreases keratin production and has been shown to reduce the number of outbreaks. Hormonal therapy may also be effective; finasteride was shown to induce remission in a small case study.

Surgical drainage provides only short-term relief because the condition has a 100% recurrence rate. Radical excision of the inflamed apocrine tissue carries a recurrence rate of 25%.

DISPOSITION

All patients with perianal hidradenitis suppurativa should be referred to a dermatologist for long-term management.

PILONIDAL DISEASE

PATHOPHYSIOLOGY

Pilonidal disease is a common disorder that generally affects young adults—those between the ages of 15 and 24 years—with a 3:1 male preponderance. Pilonidal disease often causes a considerable amount of suffering, inconvenience, and time away from work. An estimated 40,000 to 70,000 patients are treated annually, mostly as outpatients. Approximately 50% of patients with this condition are initially seen by an EP with an acute pilonidal abscess.

The term pilonidal is a combination of the words pilus, meaning “hair,” and nidus, meaning “nest.” The condition is believed to arise from hairs in the natal cleft that because of their location, grow inward rather than outward. The shafts of these hairs penetrate the skin, thereby leading to a condition of chronic inflammation and eventual infection. Chronic infection results in the formation of sinus tracts and recurrent disease.
PRESENTING SIGNS AND SYMPTOMS

The initial signs and symptoms of pilonidal disease are usually pain and swelling in the sacrococcygeal region with inability to sit on one side of the buttocks or perhaps an inability to tolerate a sitting position at all. Systemic involvement is rare. Physical examination generally demonstrates either a tender fluctuant mass over the coccyx or sacrum or a larger area of inflammation with multiple draining tracts.

DIFFERENTIAL DIAGNOSIS

Other diseases manifested as an infection or fistula must be excluded, such as rectal or perirectal abscess, Crohn disease, and hidradenitis suppurativa.

DIAGNOSTIC TESTING AND EXAMINATION

The classic clinical signs and symptoms of pilonidal disease are sufficient for diagnosis. Imaging is not useful for a typical manifestation of this condition.

TREATMENT AND DISPOSITION

Treatment is both medical and surgical. ED treatment generally consists of incision and drainage of the abscess. Simple incision plus drainage results in healing in 58% of patients within 10 weeks; of these patients, 40% have no further symptoms and 20% experience only minor symptoms. Antibiotics should be prescribed to treat any secondary cellulitis. In one study, metronidazole, 500 mg orally four times per day for 14 days, resulted in more rapid healing than did no antibiotics.

Patients with pilonidal disease can be discharged from the ED with arrangements or instructions for follow-up with a surgeon.

PROCTALGIA FUGAX

PATHOPHYSIOLOGY

Proctalgia fugax is severe, episodic anal pain. The disorder is poorly understood and difficult to treat. The pathophysiology of this condition is unclear, although it is believed to be caused by spasm of either the anal sphincter or the muscles of the pelvic floor.

PRESENTING SIGNS AND SYMPTOMS

Proctalgia fugax is usually characterized by sudden episodes of intense pain around the anal ring that can occur at any time and may last from 20 minutes to several hours. Typically, the pain occurs at night and often awakens the patient. The sensation may be associated with an urge to pass stool or flatus. Some patients may experience only one episode in their lifetime. The lifetime prevalence of this condition is 14%.

DIFFERENTIAL DIAGNOSIS

Other conditions that commonly cause rectal pain should be considered in the differential diagnosis of proctalgia fugax, such as anal fissure, hemorrhoids, perirectal abscess, and proctitis.

TREATMENT AND DISPOSITION

No specific treatment exists for proctalgia fugax. Anecdotal evidence supports the use of warm baths, topical treatment with glyceryl trinitrate, benzodiazepines, topical anesthetics, and botulinum toxin. Hot packs or direct anal pressure has also been recommended.

Patients with recurrent disease should be referred to a gastroenterologist.

PROCTITIS

PATHOPHYSIOLOGY

Proctitis is defined as inflammation of the rectal mucosa. It can involve actual loss of mucosal cells, as well as damage to the endothelium of the small arterioles supplying the mucosa. The condition may improve spontaneously, depending on the cause, or may progress with resulting tissue ischemia, mucosal friability, bleeding, ulcers, strictures, and fistula formation. Causes of proctitis are listed in Box 41.2.

PRESENTING SIGNS AND SYMPTOMS

The signs and symptoms of proctitis include fecal urgency, sensation of rectal fullness, rectalgia, pruritus, rectal bleeding (spotting), and a mucoid or purulent rectal discharge. The patient may also describe a change in bowel habits (diarrhea or constipation) and abdominal pain. Ulcers, vesicles or pustules, and strictures may be found on rectal examination.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of proctitis consists of anal fistula, anal fissure, rectal foreign body, diverticulosis, and vulvovaginitis.

DIAGNOSTIC TESTING AND EXAMINATION

Anoscopy in a patient with proctitis identifies erythema, friability, bleeding, edema, ulcers, and vesicles; rectosigmoid-
oscropy demonstrates similar findings. The following laboratory tests should be performed:

- Stool: culture and testing for ova, parasites, fecal leukocytes, and Clostridium difficile toxin
- Gonorrhea and chlamydia cultures and Gram stain of anorectal swabs
- Venereal Disease Research Laboratory or rapid plasma reagent test if syphilis is suspected

**TREATMENT**

Most cases of proctitis can be treated medically. The underlying cause, if known, should also be treated. All forms of the disorder may benefit from the following measures:

- Sitz baths
- Antispasmodic agents
- Low-residue diet
- Stool softeners

**PRURITUS ANI**

Pruritus ani is a recurrent and unpleasant itching sensation in the anal canal or perianal, perineal, vulvar, scrotal, or buttock areas. Approximately 1% to 5% of the population seeks medical attention for this condition during their lifetime. More men than women experience the disorder, which is more common in the fifth and sixth decades of life. Because of the social stigma involved, many patients attempt self-treatment before seeking care. The condition is often poorly understood and improperly treated by health care providers.

**PATHOPHYSIOLOGY**

In 50% of cases of pruritus ani, the cause is unknown. Potential causes (especially malignancy) must be excluded before the symptoms can be classified as idiopathic (Table 41.2).

**PRESENTING SIGNS AND SYMPTOMS**

Patients typically describe an itching sensation that is worse at night and during the summer months. As the patient scratches, the perianal skin is further irritated and the condition worsens. Physical findings vary with the duration of the condition and include:

- Erythema
- Whitening or cracking of the perianal skin
- Bleeding in severe cases

**DIFFERENTIAL DIAGNOSIS**

See Table 41.2. Fecal contamination of the perianal skin is the most common cause of pruritus ani.

**DIAGNOSTIC TESTING AND EXAMINATION**

Evaluation should include a careful history of potential exposures, examination of the perianal skin, digital rectal examination, anoscopy, and directed testing to exclude specific suspected causes.

**TREATMENT**

Most cases of pruritus can be treated conservatively with the following measures:

- Gentle cleansing and attention to hygiene of the perianal skin
- Modifications in diet and medications
- Brief courses of topical steroids (long-term steroid therapy should be avoided because it may thin the perianal skin and further exacerbate the condition)
- An oral antipruritic medication such as hydroxyzine or diphenhydramine

RECTAL PROLAPSE

PATHOPHYSIOLOGY

Rectal prolapse or procidentia is a circumferential protrusion of all layers of the rectum through the anus (Fig. 41.11, A). The cause is largely unclear, although the condition seems to be more common in elderly women with a female-to-male preponderance of 6:1. Predisposing factors include pelvic floor laxity, pelvic floor neuropathy, persistent straining, chronic constipation, rectal tumors, and dysfunction of the anal sphincter.

PRESENTING SIGNS AND SYMPTOMS

Actual protrusion of the rectum is the most common manifestation. Other symptoms may include anorectal pain or discomfort during defecation, sensation of incomplete evacuation, rectal and urinary incontinence, and rectal bleeding or discharge.

DIFFERENTIAL DIAGNOSIS

The EP should differentiate this condition from external hemorrhoids, prolapsed internal hemorrhoids, rectal tumors, and uterine prolapse.

DIAGNOSTIC TESTING AND EXAMINATION

Imaging is not necessary in making the diagnosis of rectal prolapse. Colonoscopy should be performed in all patients after reduction to clarify the diagnosis and further define the anatomy.

TREATMENT AND DISPOSITION

Every effort should be made to reduce the prolapsed rectum in the ED to prevent the complications of strangulation, ischemia, ulceration, or perforation. Various methods have been described for reduction, including ice packs, injection of diluted epinephrine, and manual reduction under conscious sedation or general anesthesia (Fig. 41.11, B). Applying ordinary granulated table sugar to the prolapsed tissue, a technique borrowed from veterinary medicine, has been used successfully to quickly reduce the edema and aid in reduction.16

Liver Disorders
Richard Paula

EPIDEMIOLOGY

Chronic liver disease accounts for 70,000 hospitalizations annually in the United States and is one of the top 10 leading causes of death. Almost half of the 40,000 deaths per year in the United States are related to alcohol abuse. Although the majority of deaths are due to chronic liver disease and cirrhosis, 2000 deaths per year are associated with fulminant hepatic failure. Many of these patients die while awaiting liver transplantation. Hepatitis B and hepatitis C infections account for 40% of chronic liver disease, although many of these cases are exacerbated by concomitant alcohol abuse.

Liver disease is debilitating and deadly because the liver is intimately involved in many physiologic functions. The liver (1) synthesizes coagulation factors, cholesterol, bile, and glycogen; (2) conjugates bilirubin; and (3) detoxifies exogenous chemicals such as alcohol, as well as endogenous metabolic by-products such as ammonia. Loss of any of these functions significantly impairs homeostasis.

KEY POINTS

- Causes of jaundice are best categorized by the fraction of measured bilirubin implicated in disease—unconjugated or conjugated hyperbilirubinemia.
- The possibility of cerebral edema should be considered in patients with advanced liver disease and nausea, vomiting, and changes in mental status.
- As a result of the uncertain relationship of measured serum ammonia and cerebral ammonia concentration, patients with known or suspected hepatic encephalopathy should be treated for hyperammonemia regardless of the measured level.
- The prevalence of spontaneous bacterial peritonitis is high in cirrhotic patients, with rates of 3.5% in those with no symptoms to 30% in patients who seek treatment in a hospital for any reason and undergo paracentesis.
- Hepatitis B virus immune globulin effectively prevents transmission of hepatitis B virus if administered within 72 hours of exposure; it should be given for any high-risk exposure.
- Pyogenic liver abscesses are best treated with a combination of antibiotics and percutaneous drainage. Antibiotics alone are insufficient treatment.

JAUNDICE

The most common and immediately apparent evidence of liver disease is jaundice, which is often manifested without any other symptoms.

Jaundice begins to appear when the serum bilirubin level reaches 3 mg/dL in white persons and at higher levels in darker-skinned persons. Jaundice does not require treatment in adults as it does in neonates, but instead, the cause of jaundice in adults should be investigated.

Causes of jaundice are often categorized according to the type of bilirubin implicated in disease, unconjugated or conjugated hyperbilirubinemia. In context with associated symptoms, knowledge of the fractionations of bilirubinemia aids in narrowing the differential diagnosis.

Pancreatic and biliary cancer associated with jaundice may be manifested as pain. Patients with cirrhosis from chronic hepatitis are likely to describe painless jaundice but also complain of fatigue, pruritus, and constitutional symptoms. Patients who are acutely ill with jaundice, nausea, emesis, and fever should be tested for causes of acute hepatitis; similar manifestations without fever occur in toxic ingestions.

NAUSEA

Nausea is a common extrahepatic symptom that may complicate hepatitis, toxic liver injury, cholestasis, and many other causes of acute or chronic liver disease. Management of nausea is sometimes the sole reason that a patient with acute hepatitis requires hospital admission.

Particular attention should be given to patients with known liver disease who have nausea, emesis, and changes in mental status; the emergency physician should consider the possibility of cerebral edema, especially in patients with advanced liver disease.

NEUROPSYCHIATRIC SIGNS AND SYMPTOMS

Changes in mental status in the setting of liver disease should be treated aggressively. The degree of encephalopathy is
directly correlated to the degree of liver dysfunction. Patients with a sudden change in mental status and acute hepatic insufficiency usually have an advanced stage of disease that will frequently progress to acute, fulminant liver failure.

Cerebral edema often occurs in tandem with encephalopathy because of elevated ammonia levels; immediate treatment with ammonia-clearing agents (e.g., lactulose) is required. Note that lactulose is less effective in treating mental status changes associated with acute liver failure than in treating those associated with chronic disease. Caregivers of patients with chronic hepatic insufficiency often titrate lactulose dosing in accordance with cognitive function.

**HEPATOMEGALY**

In patients with hepatomegaly, the liver becomes significantly enlarged and easily palpable as a result of sudden edema from hepatitis or the appearance of fatty infiltrates with alcohol binging. If the enlargement is significant enough to cause portal hypertension, the spleen is often enlarged and palpable as well. As the liver scars and hepatocytes are replaced by fibrous tissue in cirrhosis, the organ shrinks and eventually becomes small and nodular. The presence or absence of hepatomegaly on examination is an unreliable estimate of liver function and should not be used to exclude a particular diagnosis.3,4

**RASH**

Many patients with liver disease complain of skin irritation. Hepatitis has been associated with livedo reticularis, a lacy, erythematous rash caused by capillary spasm. Dermatitis caused by autoimmune hepatitis that promotes jaundice has an intense pruritic component. Patients with liver disease may be unable to control scratching, and infections develop in the self-induced excoriations. Finally, patients may complain of a “rash” that represents ecchymosis secondary to coagulopathy; such bruising without reported trauma should raise concern for advanced liver disease.

**ASCITES**

Ascites is the abnormal accumulation of peritoneal fluid, a common feature in patients with advanced liver disease. The exact pathogenesis of ascites has not been established, but multiple theories focus on the interaction of the liver with ammonia. In patients with advanced liver disease and cirrhosis, however, mental status may not correlate directly with measured ammonia levels. Ammonia tends to accumulate in the brain, and although blood levels may be normal, the patient may still have enough ammonia in cerebrospinal fluid to induce encephalopathy.

Because of the uncertain relationship of the measured serum ammonia and cerebral ammonia concentration, patients with known or suspected hepatic encephalopathy should be treated for hyperammonemia regardless of measured serum levels. No convincing evidence suggests that arterial sampling for measurement of ammonia is superior to venous measurements.7

**TREATMENT**

Emergency department (ED) management of hepatic encephalopathy consists of appropriate airway control and resuscitation, followed by the administration of ammonia-lowering agents. Lactulose (15 to 45 mL once or twice daily) is the most common treatment of choice in the United States, although sodium benzoate has been shown to be equally effective and less expensive.11 Lactulose is a nonabsorbable disaccharide that decreases intestinal transit time through a direct cathartic effect, thus lowering intestinal bacterial loads. Lactulose also lowers intestinal pH, which favors competitive non-ammonia-producing bacteria. Lactulose may be given orally, by nasogastric tube, or in severely obtunded patients, as a retention enema.12

Neomycin is a poorly absorbed aminoglycoside used as secondary treatment to further reduce intestinal bacterial counts. Even though it is poorly absorbed, neomycin does cause systemic toxicity and should be used only when lactulose is ineffective. Mannitol (0.5 to 1 g/kg) effectively reduces cerebral edema and improves survival in patients with hepatic encephalopathy secondary to acute liver failure.8,13

The following therapies have been shown to be ineffective and should be avoided: hyperventilation,8,14 corticosteroids,8,13 and terlipressin.15

**SIGNS AND SYMPTOMS OF ADVANCED LIVER DISEASE**

**ENCEPHALOPATHY**

Changes in mental status may occur with either acute or chronic liver disease. The pathophysiology of hepatic encephalopathy is not completely understood, but it is clear that pronounced encephalopathy is associated with poor outcomes. Although many chemical markers have been implicated as the cause of hepatic encephalopathy, most studies identify two important factors, γ-aminobutyric acid (GABA) and ammonia (NH₃).

Serum GABA levels are elevated in patients with cirrhosis. Administration of a GABA receptor antagonist (flumazenil) results in transient but significant improvements in cirrhotic patients’ mental status.

The second and more easily measurable toxicity results from an increased ammonia concentration. The serum ammonia concentration rises as liver function declines, with intermittent fluctuations occurring in chronically ill patients. Many factors affect ammonia production, including changes in diet, constipation, hepatorenal syndrome, and gastrointestinal bleeding. Ammonia readily crosses the blood-brain barrier, and in patients with hepatic encephalopathy, ammonia causes cerebral toxicity, which promotes mental status decline and eventually coma.5,7

Ammonia is clearly toxic, and in animal models, ammonia infusions alone have been directly linked to the development of cerebral edema. In the setting of acute liver failure, ammonia levels higher than 200 mcg/dL are strongly associated with the development of cerebral edema and herniation.8-10 In patients with advanced liver disease and cirrhosis, however, mental status may not correlate directly with measured ammonia levels. Ammonia tends to accumulate in the brain, and although blood levels may be normal, the patient may still have enough ammonia in cerebrospinal fluid to induce encephalopathy.

**SECTION IV GASTROINTESTINAL DISEASES**
various other organ systems. The combination of portal hypertension and decreased albumin production contributes significantly to the accumulation of ascitic fluid.

Ascites associated with cirrhosis has a poor prognosis. One episode of ascites has a 3-year mortality rate of 50%, and recurrent ascites has the same 50% mortality at 1 year.16,17 Comorbid conditions contribute to mortality, including the development of hepatocellular carcinoma, gastrointestinal hemorrhage, coma, and infection.

One important infectious cause of death in patients with ascites is spontaneous bacterial peritonitis (SBP). The prevalence of SBP in cirrhotic patients is high, with rates of 3.5% in asymptomatic patients to 30% in patients who seek treatment in a hospital for any reason and undergo paracentesis.18,19

Paracentesis for the relief of tense ascites has been shown to improve cardiac function.20 Reduction of intraabdominal hypertension and resolution of an effective abdominal compartment syndrome improve venous return to the heart.21

Patients with symptomatic ascites require paracentesis. Given the high rate of occult SBP in these patients, peritoneal fluid should always be sent for analysis. Previously, it was thought that large-volume paracentesis was associated with complications and should be avoided, but this common misperception has been disproved. Large-volume (>5 L) paracentesis is safe and is associated with shorter hospitalization than is the case with diuretic therapy in patients with refractory ascites.22,23

Complications of paracentesis are rare, even in thrombocytopenic patients. Most complications involve bleeding or persistent leakage from the puncture site and occur within 24 hours. Patients with such complications should be admitted to the hospital for observation.24,25

Controversy exists regarding volume expansion with colloids in conjunction with paracentesis. Studies have not demonstrated any short-term improvements in mortality or morbidity with the use of plasma expanders, although some alterations in renal function, such as elevations in blood urea nitrogen and decreased sodium levels (both of which are associated with a worse prognosis), have been observed. Albumin is the least expensive, safest, and usually most effective colloid for intravascular volume expansion and should be used in patients with paracentesis volumes of 5 L or larger.26,28

Paracentesis is improved when ultrasonography is used to identify ascites and guide the paracentesis. In one study, paracentesis performed under ultrasonographic guidance was successful in 95% of patients as opposed to 65% of procedures without such guidance.29

Outpatient treatment of ascites should center on dietary sodium restriction in combination with diuretics. Management by a primary care physician includes frequent checks of potassium and sodium levels, both of which have been implicated in morbidity in these patients. Patients with recurrent ascites should be referred for surgical evaluation for a possible transjugular intrahepatic portosystemic shunt procedure.

**SPONTANEOUS BACTERIAL PERITONITIS**

Symptoms of SBP are often vague. Although abdominal pain and fever are common, both may be absent. Patients may complain only of increased fatigue, myalgia, worsening ascites, or decline in mental status.

SBP is thought to be caused by translocation of intestinal flora, although this long-held premise is now under question. Previously, SBP was almost entirely associated with gram-negative bacteria, mostly *Escherichia coli*; a growing number of patients with SBP now have gram-positive organisms.30

The diagnosis is confirmed by culture of peritoneal fluid aspirated during paracentesis. SBP is likely if peritoneal fluid neutrophil counts are greater than 250 cells/µL. Peritoneal fluid lactate levels may be even more accurate.26,27

Patients with suspected SBP should have as much fluid drained as possible. Empiric antibiotic treatment should begin as soon as the diagnosis is considered. SBP in cirrhotic patients carries a mortality rate of 20% to 40%, with a 1-year survival rate of just 40%.26 Treatment should begin with a third-generation cephalosporin, such asceftriaxone or cefotaxime. Quinolones should not be used because bacterial resistance to these agents is high and will worsen if the incidence of gram-positive infections continues to rise. Failure rates have been increasing regardless of which antibiotic regimen is used—it is often necessary to tailor individual therapy to the organisms found on culture.31

**CIRRHOSIS**

Continued liver injury results in irreparable damage with permanent loss of liver function and subsequent chronic disease states. Cirrhosis is the common end point of many chronic liver diseases characterized by the replacement of functioning hepatocytes with physiologically inactive fibrotic tissue. Patients with cirrhosis may have any number of symptoms or clinical conditions related to end-stage liver disease.

**PORTAL HYPERTENSION**

Portal hypertension occurs when intraportal pressure is elevated 10 mm Hg above normal throughout the portal system. The cause is multifactorial, and the disorder can occur with conditions other than cirrhosis.

Parasitic infections are an extremely common cause of reversible portal hypertension in developing countries. Parasites, commonly those responsible for schistosomiasis, cause chronic inflammatory states in the portal sinuses that lead to granuloma formation and fibrosis.

Portal hypertension develops in patients with cirrhosis because of increased intrahepatic resistance to greater portal flow. Numerous cellular disorders occur simultaneously in cirrhotic patients with increased portal pressure. Lack of intrahepatic vasodilation is caused by fibrocyte deposition and decreased nitric oxide production within the liver. Increased portal flow results from higher cardiac output and splanchnic flow associated with extrahepatic nitric oxide production. The greater pressure causes deposition of peritoneal fluid and redirection of blood flow. As these forces coincide, blood is rerouted around the liver to compensate. Collateral flow increases as portal pressure rises; pressures greater than 12 mm Hg promote the formation of *varices*—chronically dilated veins in the collateral bed that shunt blood flow away from the liver. Varices occur in the following locations:
Abdominal wall: Varices involving the abdominal wall are called caput medusae, so named for their serpentine appearance. They arise from dilation of the abdominal wall and umbilical veins.

Rectum: Hemorrhoids represent a form of rectal varices. They are often friable and subject to significant bleeding.

Esophagus: Esophageal varices are a common source of gastrointestinal bleeding in patients with portal hypertension. Bleeding may be massive and difficult to control because of concomitant coagulopathy.

Cirrhotic patients have impaired excretion of free water. Low sodium levels, found in a third of all patients with cirrhosis, contribute to ascites, frequent falls, and cognitive decline. Hyponatremia is associated with a decreased response to diuretic therapy and a poor prognosis. In 2009 the U.S. Food and Drug Administration approved the novel drug tolvaptan for the treatment of hyponatremia; tolvaptan acts as a vasopressin antagonist. As with any new pharmaceutical class, data are limited, but the early results are promising.

Hepatorenal syndrome exists as a chronic debilitating state or as a rapidly progressive and terminal condition. This syndrome occurs when kidney function declines in the setting of liver failure. All patients with cirrhosis have some degree of renal insufficiency; most continue to decline slowly, whereas others progress rapidly to renal failure.

Hepatorenal syndrome is diagnosed in a patient with cirrhosis who also has a rise in creatinine levels to more than 1.5 mg/dL in conjunction with a serum sodium level lower than 130 mEq/L. SBP, acute alcoholic hepatitis, and hypotension are common precipitants of this syndrome. Although hepatorenal syndrome frequently develops in patients being treated for SBP, some evidence has shown that administering albumin as a component of SBP management reduces the likelihood of development of this syndrome.

Liver transplantation is the only therapy that has been shown to reduce mortality in patients with fulminant hepatorenal syndrome.

Hepatitis A virus (HAV) is a single-stranded RNA enterovirus in the disease-producing family Picornaviridae, which also includes poliovirus. Also known as epidemic hepatitis because of its ability to spread swiftly and suddenly, HAV infects an average of 60,000 individuals annually worldwide. Transmission is fecal-oral, as in settings such as day care, or through sexual contact. It may also be transmitted by contaminated water or food sources; shellfish is a common vector, although seemingly innocuous food sources, such as imported lettuce, have been implicated in outbreaks as well.

**SYMPTOMS, SIGNS, AND DIAGNOSTIC TESTING**

Incubation may be as long as 30 days. Symptoms include anorexia, nausea, emesis, diarrhea, fever, and eventually jaundice. Serum IgM titers are diagnostic of HAV infection.

**TREATMENT AND PROGNOSIS**

Treatment of HAV infection is supportive. Most infections are subclinical, and full recovery is expected in more than 99.5% of those infected. A vaccine is commercially available for HAV and is recommended for persons traveling to endemic areas. HAV immune globulin may be used up to 2 weeks after exposure; it is generally reserved for high-risk patients, such as those with preexisting infectious hepatitis (other than HAV), elderly patients, and immunocompromised individuals.

**DISPOSITION**

Patients infected with HAV may need to be admitted to the hospital for parenteral control of vomiting and administration of fluids. Liver function values are often markedly elevated, although this finding is not an indication for admission.

**HEPATITIS B VIRUS**

Hepatitis B virus (HBV) is a double-stranded DNA virus that has a cross-species reservoir. It infects human, ducks, and squirrels. HBV is transmitted person to person through sexual contact, blood exposure, transfusion, and perinatal vertical transmission. It is highly virulent—infec tion may be caused by a small number of virions. HBV is easily passed through contaminated needles, either from needle sharing among drug abusers or through occupational exposure in health care workers.

More than 1 million individuals have chronic HBV infection in the United States, and approximately 500 million are infected worldwide. From 1990 to 2004, the overall incidence of reported acute HBV infection declined 75% through vaccination efforts, from 8.5 to 2.1 per 100,000 persons.

**SYMPTOMS AND SIGNS**

Acute infection with HBV causes anorexia, nausea, emesis, diarrhea, fever, and eventually jaundice. Serum levels of alanine transaminase (ALT) and aspartate transaminase (AST) may both rise to greater than 10,000 U/L and cause constitutional symptoms that precede the appearance of jaundice.

**DIAGNOSTIC TESTING**

HBV infection can be defined as acute, chronic, or carrier. If the patient has not been immunized against HBV and has not previously shown signs of the disease, the presence of hepatitis B surface antigen and expected symptoms confirms the diagnosis of acute infection.
TREATMENT AND PROGNOSIS

The prognosis of patients with HBV infection varies widely, although most individuals (90% to 95%) recover completely. Up to 10% of patients enter a chronic infectious state and are at risk for cirrhosis and hepatocellular carcinoma. Approximately 2% die of fulminant hepatic failure.

Multiple drug regimens exist for the treatment of HBV, most notably peginterferon alfa-2b with or without lamivudine. Such regimens have never been shown to be effective in the acute setting, and recommendations are to withhold treatment until evidence of ongoing viral replication is present.

HBV immune globulin (HBV-IG) effectively prevents transmission if given within 72 hours of exposure and should be administered to patients after high-risk exposure. Centers for Disease Control and Prevention guidelines recommend administration of HBV-IG and HBV vaccine to unvaccinated health care workers exposed to patients known to have HBV and administration of HBV-IG to persons with unknown HBV status after high-risk exposure. Nonoccupational postexposure prophylaxis should follow similar recommendations (e.g., sexual assault or coincident with human immunodeficiency virus postexposure prophylaxis).

DISPOSITION

Patients with HBV infection may require admission for parenteral control of vomiting and administration of fluids. Evidence of possible hepatic failure is reflected in prolongation of the prothrombin time (PT), which should be measured if HBV infection is suspected. Liver function values are often markedly elevated, but this finding is not an indication for admission.

HEPATITIS C VIRUS

An RNA virus that is extremely complex and diverse, hepatitis C virus (HCV) has at least six distinct genotypes and 50 subtypes. This genetic diversity complicates development of a vaccine against it. HCV infection is the leading reason for liver transplantation; chronic infection commonly causes cirrhosis and hepatocellular carcinoma. Transmission occurs through sexual contact and sharing needles with infected individuals.

HCV transmission peaked in the United States in the 1980s before its discovery, with an estimated 250,000 new cases per year in that decade. Infection rates have dropped to approximately 40,000 annually. Carriers with chronic HCV infection number almost 3 million.40 The prevalence of HCV in trauma patients is 15% to 20%.41,42

DIAGNOSIS

Unlike acute infection with HAV or HBV, acute HCV infection is much more likely to pass without symptoms—up to 80% of infected persons are asymptomatic. HCV can produce a flulike illness that is easily ignored. It is ultimately diagnosed with anti-HCV antibody screening, which is confirmed by polymerase chain reaction for HCV RNA.

TREATMENT AND PROGNOSIS

HCV is much more destructive than either HAV or HBV. Approximately 15% of infected persons fully recover, but cirrhosis develops in 15% and hepatocellular carcinoma eventually develops in 5%. HCV accounts for 50% of cases of cirrhosis diagnosed in the United States.

Treatment with various drug regimens is available, although none are recommended for use in the ED in patients with suspected infection. Viral replication must be verified and serotyped to guide treatment. Neither vaccine prophylaxis nor postexposure prophylaxis is currently available.

DISPOSITION

Patients infected with HCV may have to be admitted to the hospital for parenteral control of vomiting and administration of fluids. Evidence of possible hepatic failure is reflected in prolongation of the PT, which should be measured if HCV infection is suspected. Liver function values are often markedly elevated, but this finding is not an indication for admission.

AMEBIASIS

Amebic liver infections are of growing concern in the United States, although the infection is much more prevalent in the developing world. Amebiasis affects 50 million persons worldwide and is estimated to cause 50,000 to 100,000 deaths per year.41 Amebiasis is frequently manifested as colitis. It is unknown what percentage of cases progress to abscess formation, although approximately one third of patients with abscesses have prodromal nausea, emesis, diarrhea, and bloating.44 Solitary abscess formation is common in patients with amebic abscesses, as opposed to the multiple foci often seen in those with pyogenic abscesses. Amebic abscesses have a predilection for males, with a 10 : 1 ratio of infection; such gender bias is not seen with pyogenic abscesses.

DIAGNOSIS

Most patients in the United States in whom amebic liver abscess is diagnosed are seen in the southwestern states and are males of Mexican origin.46 The symptoms may mimic those of cholecystitis, with right upper quadrant abdominal pain, fever, chills, and nausea. In one series, 20% of patients with amebiasis had isolated pulmonary complaints.46

Abscesses are easily seen on ultrasonography. The ultrasonographic appearance in combination with acute symptoms makes the diagnosis in at least two thirds of patients.45,47,48 Computed tomography (CT) is sensitive as well and should be used when the diagnosis is in question.

Tests for Entamoeba histolytica—specific antibodies should be performed if an amebic abscess is suspected.

TREATMENT AND PROGNOSIS

Metronidazole remains the first-line treatment (a high-dose schedule consisting of 750 mg three times daily for 10 days provides a 90% cure rate).47 Aspiration has traditionally been recommended for abscesses larger than 5 cm, although the results of studies examining this practice are equivocal.48,49
Liver abscesses in the United States and worldwide are most often due to amebiasis, although pyogenic abscesses represent a more serious condition. Pyogenic abscesses were diagnosed in 3000 patients per year in one European study. Patients with pyogenic abscesses are more ill, have multiple abscesses, and suffer a worse prognosis than do those with amebic abscesses. Unlike those with amebic abscesses, approximately 50% of patients have multiple pyogenic abscesses, either from hematogenous spread (as a result of infections such as diverticulitis) or through direct extension from suppurative cholangitis (now thought to be the most common cause).

Bacterial causes of pyogenic abscess are diverse and include E. coli, Klebsiella, Staphylococcus aureus, and various anaerobes. Patients with pyogenic abscesses are much less likely to have the classic symptoms of liver abscesses seen with amebic infections, such as right upper quadrant pain, fever, nausea, and vomiting.

Because the causes of pyogenic abscesses are so varied, the abscesses are not manifested in a uniform fashion. Right upper quadrant tenderness and hepatomegaly are noted in approximately 50% of cases. Patients commonly show signs of systemic disease, such as fever, malaise, weight loss, and anorexia.

Liver function values may or may not be elevated and should not be used to exclude the diagnosis. Ultrasonography and CT are both excellent imaging modalities, with sensitivities of 85% and 95%, respectively.

Pyogenic liver abscesses are treated with a combination of antibiotics and drainage. Catheter drainage and needle aspiration produce similar success rates of 60% to 90%, although these two options have not been compared directly. The largest published trials have demonstrated success rates exceeding 95% with ultrasound-guided aspiration without catheter placement followed by broad-spectrum intravenous antibiotics (to cover gram-positive, gram-negative, and anaerobic organisms). Antibiotic therapy without abscess drainage is generally unsuccessful.

Even with appropriate therapy, the mortality rate in patients with pyogenic abscesses is 5% to 10%. Any patient with a suspected pyogenic abscess must be admitted to the hospital.
inflammatory changes that induce scarring and permanent replacement of functional hepatocytes with lipocytes and fibrous tissue. The smaller numbers of hepatocytes cannot handle the physiologic requirements of the body. This pathologic progression is significantly accelerated by coexisting HCV or HBV infection. Women are much more prone to alcohol-induced hepatic injury. Acute hepatitis secondary to alcohol consumption is termed alcoholic hepatitis or alcoholic steatohepatitis. Steatohepatitis, so named from the overwhelming fatty infiltration seen with alcohol metabolism, is associated with impairment of liver function. Acute alcoholic hepatitis is common in heavy, chronic, binge-type alcohol users.

### DIAGNOSIS

Patients with alcoholic hepatitis often admit to heavy alcohol use and may appear jaundiced or complain of dark urine. Constitutional symptoms are common—weakness, nausea, emesis, and malaise. Patients often display signs of chronic liver insufficiency, including asterixis and spider angiomas.

### TREATMENT AND PROGNOSIS

Treatment is mostly supportive, although as with other forms of liver disease, both coagulopathy and changes in mental status should be treated aggressively. The mortality rate in hospitalized patients with alcoholic hepatitis is approximately 10%. Higher mortality is observed when patients have concomitant encephalopathy and coagulopathy; immediate liver transplantation may be required for their survival.

Corticosteroid use in hospitalized patients with alcoholic hepatitis is controversial. During the 1980s and early 1990s, a number of published studies proclaimed significant reductions in mortality with the use of corticosteroids (particularly convincing was one study of the use of prednisolone in 1992). However, a carefully performed metaanalysis published in 1995 that examined 12 controlled trials did not find any benefit. The use of corticosteroids should be reserved for inpatient units and not be initiated in the ED.

### DISPOSITION

Admission to the hospital is necessary for patients with acute alcoholic hepatitis because of high mortality rates and a significant need for transfusion, vasopressors, and aggressive resuscitation.

### AUTOIMMUNE LIVER DISORDERS

The two major immunologic causes of liver disease are autoimmune hepatitis and primary biliary sclerosis. Patients with immune-related liver disease are mostly female and show signs of autoimmune disease, as well as liver disease. The clinical signs regularly include myalgia, polyarthritis, rash, and findings consistent with other autoimmune disorders, such as Sjögren syndrome and systemic lupus erythematosus.

Patients with autoimmune liver disorders have progressive disease and a survival rate of 10% to 50% at 5 years if untreated. As the disease advances, the patient exhibits signs of liver insufficiency similar to those in other patients with chronic liver disease.

These diseases are difficult to detect and differentiate from other forms of chronic liver disease—such differentiation is not a goal of ED care.

Management of patients with autoimmune liver disorders is complicated by the immunosuppressive drugs used for treatment (prednisone and azathioprine are most commonly prescribed). When caring for patients in the ED, the clinician must consider complications of immunosuppressive therapy and administer stress-dose corticosteroids when required.

The prognosis has improved with liver transplantation, which provides a 10-year survival rate of 75%; recurrence is seen in 42% of patients.

### DRUG-INDUCED LIVER DISEASE

Many pharmaceutical and naturally occurring substances can cause catastrophic liver injury (Box 42.1). The manifestation of drug-induced liver disease varies from benign jaundice to fulminant hepatic failure. Almost 40% of cases of acute hepatic failure in the United States are caused by drug-induced injury; almost half of these cases are due to acetaminophen alone.

#### Care of Patients with Liver Transplants

More than 36,000 patients living in the United States have undergone liver transplantation. Transplantation patients come to the ED with common complaints, such as fever and abdominal pain, which are associated with high morbidity in this population. Almost 70% of liver transplant recipients who seek care in an ED require hospitalization.
Transplant recipients are immunosuppressed, and any fever must be taken seriously. Serious febrile illnesses associated with liver transplantation are bacteremia and pneumonia; otitis media is common. Immunosuppressive medications also raise the risk for viral and fungal infections.

### INFECTIOUS COMPLICATIONS

The most common serious infection seen in the first few months after transplantation is cytomegalovirus, which is manifested as fever, arthralgias, and malaise. Other viral infections, such as herpes simplex virus, varicella-zoster virus, and herpes zoster virus, are also common but are not as serious as cytomegalovirus. Infections with fungi such as *Candida* should also be suspected.

Serious infections may be present in the absence of fever or leukocytosis. Half of liver transplant recipients with the eventual diagnosis of a serious infection had neither a fever nor an elevated white blood cell count.

### MECHANICAL COMPLICATIONS

Liver transplant recipients are subject to vascular or structural problems surrounding and within the transplant. Hepatic artery stenosis and hepatic artery thrombosis are each present in approximately 10% of liver transplant recipients, frequently because of rejection. Either stenosis or thrombosis of the hepatic artery can be manifested as abdominal pain, and both are accurately detected with ultrasonography.

Timely discussion with a transplant team and early use of angiography are recommended because of the need for a rapid decision on corrective treatment.

The portal system may also be affected; ultrasonography should be used to evaluate the portal system at the time that the arterial system is examined because another 10% of liver transplant recipients have portal vein or hepatic vein thrombosis. Magnetic resonance venography is needed to confirm suspected portal or hepatic vein thrombosis.

Finally, the biliary tree is also affected by stenosis or ischemia in approximately 10% of patients and is diagnosed by ultrasonography or angioiography.

### Liver Function Tests

Liver function may be measured indirectly through a variety of laboratory tests. Laboratory abnormalities are neither specific nor sensitive and can therefore be misleading; however, certain abnormalities can help guide the astute physician toward further diagnostic testing in search of a specific diagnosis.

### ALANINE TRANSAMINASE AND ASPARTATE TRANSAMINASE

Both ALT and AST, which are called transaminases, are concentrated intrahepatocyte enzymes (although AST exists in

measurable quantities elsewhere in the body as well). Any hepatocyte necrosis elevates these enzymes. The often quoted 2:1 ratio of AST to ALT in patients with alcoholic liver disease is not supported by the literature.71,74

Chronic disease states such as HCV, alcoholic cirrhosis, and autoimmune hepatitis are often associated with persistent elevations in ALT and AST, although normal values should not be used to exclude the possibility of disease. More than 15% of patients with biopsy-proven chronic HCV disease have transaminase elevations.75

### ALKALINE PHOSPHATASE AND γ-Glutamyltransferase

Both alkaline phosphatase (AP) and γ-glutamyltransferase (GGT) are markers of cholestasis. However, AP is present at significant levels in many other organ systems—bone, intestine, and placenta. AP values are elevated in normal pregnancy and with metastatic disease involving bone (e.g., prostate cancer). Children also have physiologically normal elevations in AP during growth. GGT is much more highly concentrated in the liver and can be used in conjunction with AP to determine whether an abnormality is intrahepatic or extrahepatic.

### PROTHROMBIN TIME

The PT measures the activity of certain clotting factors in both the intrinsic and extrinsic pathways. The liver is the primary site for manufacture of these clotting factors, and decreases in synthesis by an impaired liver can be inferred from a prolonged PT. Vitamin K is a cofactor in clotting factor synthesis, and medications that block its absorption, such as warfarin, prolong PT values.

### BILIRUBIN

Bilirubin exists in two distinct forms, conjugated (direct) and unconjugated (indirect). Bilirubin is a by-product of hemoglobin metabolism. Unconjugated bilirubin is present in serum bound to albumin in a water-insoluble state. It is transported to the liver, where it is conjugated with glucuronide in preparation for excretion into bile.

Understanding this process of bilirubin metabolism helps focus the differential diagnosis of patients with hyperbilirubinemia or jaundice, or with both (Tables 42.1 and 42.2). Unconjugated hyperbilirubinemia results from increased production of bilirubin (hemolysis) or from decreased uptake in the liver (as seen in various inherited conditions). Conjugated hyperbilirubinemia results from loss of excretory capacity, which can occur as a result of intrahepatic diseases (e.g., drug reactions, hepatitis, cirrhosis) or biliary obstruction. Obstructive jaundice is due to a lesion that blocks the excretion of bile through the biliary ducts, either proximally at the hepatic duct or more distally at the common bile duct.73,76

Pancreatic Disorders

Mitchell C. Sokolosky

Pancreatitis is an inflammatory condition of the pancreas that results from premature activation of pancreatic enzymes and autodigestion of the gland. The exact pathogenesis of this disease is unclear. Both acute and chronic forms exist.

Acute pancreatitis is most often caused by gallstones or alcohol use. Gallstone pancreatitis occurs secondary to obstruction of the common bile or pancreatic duct. Alcohol or its metabolic by-products are thought to act as a direct toxin to the pancreas, and the effects are usually dose dependent. Other less common causes are hyperlipidemia, hypercalcemia, medications, toxins, trauma, surgery, sphincter of Oddi dysfunction, invasive diagnostic procedures (endoscopic retrograde cholangiopancreatography), and hereditary causes. Approximately 20% of cases are idiopathic, with occult microlithiasis thought to be the underlying cause in half of them. Acute pancreatitis can be classified histologically as edematous or necrotizing, which corresponds to clinically mild or severe disease, respectively. Risk factors for severe disease include older age (>55 years), obesity (body mass index > 30 kg/m²), and pleural effusions or infiltrates (or both). Pancreatic necrosis (nonviable tissue) is associated with significant morbidity and mortality, especially if infection is present. Complications from pancreatitis include pseudocyst and abscess formation.

Chronic pancreatitis is often a progressive disorder with irreversible lesions, such as glandular fibrosis, distortion of the pancreatic duct, and strictures. Long-standing alcohol abuse is the most common cause of chronic pancreatitis.

Standard definitions and terminology for acute pancreatitis (Table 43.1) have been proposed to establish an exact vocabulary among institutions and within the literature.

1. Provide aggressive intravenous hydration to treat or prevent hypovolemia.
2. Provide appropriate parental narcotics for pain control.
3. Consider computed tomography if concerned about other possible serious causes of abdominal pain, such as a perforated ulcer.
4. Consider admission to the intensive care unit for patients with organ failure.
5. Start broad-spectrum antibiotics for clinical evidence of sepsis.
PRESENTING SIGNS AND SYMPTOMS

CLASSIC
Acute pancreatitis is manifested as severe, upper abdominal pain that may radiate to the back. The onset of pain is rapid, typically over a period of an hour or less. The pain is constant and is often worsened by lying flat and partially relieved by sitting up. Nausea and vomiting are typically present. Fever and anorexia may or may not be present. Jaundice is rare. Findings on examination vary with the severity of disease. Abdominal examination usually demonstrates a soft, tender epigastrium without peritoneal signs. Guarding or rebound tenderness suggests more severe disease. Distention may be present secondary to concomitant ileus.

VARIATIONS
Painless pancreatitis may be encountered in the postoperative period after major surgery or in association with peritoneal dialysis or legionnaires disease. Though rare, ecchymoses in the flanks (Grey Turner sign) or in the periumbilical area (Cullen sign) from intraabdominal hemorrhage suggest severe disease. Diaphragmatic irritation from an inflamed pancreatic tail may produce hiccups and pleural effusions. Patients with necrotizing pancreatitis may arrive at the emergency department (ED) in shock or coma.

DIFFERENTIAL DIAGNOSIS
The differential diagnosis for pancreatitis includes peptic ulcer disease with or without perforation, gastritis, biliary colic, acute cholecystitis, aortic dissection, mesenteric ischemia, myocardial infarction, and renal colic.

DIAGNOSIS
Diagnosis of acute pancreatitis requires two of the following three features: (1) characteristic abdominal pain, (2) elevated serum pancreatic enzymes, and (3) characteristic findings on computed tomography (CT).7

LABORATORY TESTS
No biochemical marker is considered the “gold standard” for diagnosis or assessment of the severity of acute pancreatitis.9 Serum amylase and lipase measurements remain important diagnostic tests for acute pancreatitis. Other useful prognostic tests are a complete blood count; measurements of blood urea nitrogen and serum electrolyte, creatinine, glucose, and triglyceride levels; and liver function tests. Total serum amylase has a reported sensitivity of 83% and specificity of 88% for acute pancreatitis.10 Amylase levels rise within 6 to 12 hours of onset and usually remain elevated for 3 to 5 days. A normal amylase value would generally exclude the diagnosis of acute pancreatitis except in cases involving hyperlipidemia, acute exacerbations of chronic pancreatitis, or markedly delayed manifestations (in which case amylase levels may have normalized). Acute pancreatitis should not be excluded on the basis of a normal or mildly elevated amylase value when clinical suspicion of this diagnosis is high. Serum amylase values cannot be used to estimate the severity or determine the cause of acute pancreatitis. Nonpancreatic causes of elevated serum amylase levels are listed in Box 43.1.

The serum lipase level is more sensitive (92%) and specific (96%) than total amylase for acute pancreatitis.10 Lipase has
greater sensitivity in patients with acute alcoholic pancreatitis. It is useful in delayed clinical manifestations because the serum lipase value stays elevated longer than the serum amylase value does. However, serum lipase is not as specific for acute pancreatitis as once thought. The value is elevated in as many disorders as the amylase value (Box 43.2). As with serum amylase values, serum lipase values cannot be used to estimate the severity or determine the cause of acute pancreatitis.

Controversy exists whether measurements of serum amylase, serum lipase, or both should be ordered in a patient in whom pancreatitis is suspected. Within 24 hours after the onset of symptoms, both enzyme values have high sensitivity and specificity for acute pancreatitis. Simultaneous evaluation of these two serum enzymes has not been shown to increase overall diagnostic accuracy, and the extent of elevation in pancreatic enzyme levels does not correlate with the severity of disease. The serum lipase value is thought to have higher diagnostic accuracy because it remains elevated longer than serum amylase does.

A uniform threshold has not been established for serum amylase or lipase for the diagnosis of acute pancreatitis, but most of the published literature has reported thresholds of two to four or more times the upper limit of normal. However, the diagnosis of acute pancreatitis should not rely solely on elevations in serum enzymes above the arbitrary limit of normal laboratory levels but instead should be made on the basis of the onset of clinical symptoms because the sensitivities of these enzyme values change with the timing of their measurements.10

The urinary dipstick test for detecting pancreatic amylase in urine has demonstrated a sensitivity of 97%. This test for amylase may therefore be a useful point-of-care screening test for acute pancreatitis in the ED but is currently not in widespread use.11

C-reactive protein (CRP) is the best available serum marker for assessing the severity of acute pancreatitis.4 A threshold level greater than 150 mg/L is now accepted as a proven predictor of severity. However, CRP levels must be monitored after hospital admission because it takes 48 to 72 hours for the value to peak, thus making it less useful in the ED.

Hemoconcentration secondary to volume depletion has been identified as an early marker of pancreatic necrosis. In one study, an admission hematocrit value of 47% or higher and failure of the value to decrease at 24 hours after admission were associated with the development of pancreatic necrosis.12 An increase in serum alanine transaminase levels to higher than 150 IU/L is suggestive of gallstone pancreatitis.13 A lower value does not exclude the diagnosis, however.

Measurement of isoamylases, immunoreactive trypsinogen, macroamylases, or elastase has no role in the routine management of acute pancreatitis in the ED.14

**IMAGING**

Plain abdominal radiographs are rarely useful except to exclude other causes of abdominal pain such as perforation and obstruction. Positive findings in acute pancreatitis include the presence of a sentinel loop (an area of focal ileus) or a colon cutoff sign (a paucity of colonic air distal to the splenic flexure caused by functional spasm of the descending colon secondary to pancreatic inflammation). Pancreatic calcifications can be seen on radiographs in patients with chronic pancreatitis.

CT of the abdomen can aid in the diagnosis of acute pancreatitis and its complications, as well as assess the severity of disease. Most ED patients with acute pancreatitis do not require a CT scan at admission unless it is needed to exclude other serious causes of acute abdominal pain, such as a perforated ulcer. Contrast-enhanced CT of the abdomen is considered the best available test for the noninvasive diagnosis of pancreatic necrosis.15 Necrosis may develop several days after admission and should be suspected in patients with clinical evidence of increased severity. Affected portions of the necrotic pancreas do not show normal contrast enhancement on CT (Fig. 43.1). Non–contrast-enhanced CT will not aid in the diagnosis of pancreatic necrosis but may be considered in patients with renal insufficiency to provide other useful information. CT can diagnose complications such as pseudocysts (Fig. 43.2), phlegmon, and abscesses.
Ultrasonography has a limited role in the diagnosis of pancreatitis. Findings positive for acute pancreatitis include a diffusely enlarged, hypoechoic pancreas. Ultrasonography is very useful for imaging the biliary tract and diagnosing gallstones.

Magnetic resonance imaging (MRI) has been used in the diagnosis and management of acute pancreatitis. This modality is superior to CT in its categorization of fluid collections, necrosis, abscess, hemorrhage, and pseudocysts. Disadvantages include the lack of availability of MRI when urgently needed and the difficulty of caring for critically ill patients undergoing MRI.

Criteria for Determining Severity

The two most important markers of severity in acute pancreatitis are the presence of organ failure because of the systemic release of local inflammatory mediators (i.e., shock, pulmonary insufficiency, renal failure, gastrointestinal bleeding) and pancreatic necrosis.

Contrast-enhanced CT of the abdomen is considered the best available test for determining the severity of disease, particularly after 2 to 3 days of illness. A CT Severity Index Score can be calculated on the basis of CT findings, with a score of 6 or higher indicating severe disease (Table 43.2).

Though not as accurate as the CT system, scoring systems that include clinical criteria may also be used to estimate severity but have a limited role in the ED because of either timing or the complexity of the data elements. The most commonly used clinical scores for determining the severity of acute pancreatitis are the Ranson criteria (Box 43.3) and the second version of the Acute Physiology and Chronic Health Evaluation (APACHE II).

The Ranson score is based on 11 prognostic signs. Five of the signs are measured on admission, and six are measured 48 hours later, thus making it less useful in the ED setting. Mortality estimates are based on the number of signs present. Mortality is less than 0.9% when three or fewer signs are present; it is 100% when more than six signs are noted.

The APACHE II score is based on 12 physiologic variables, age, and previous health. The APACHE II score is probably the best clinical predictor of the severity of acute pancreatitis. A severity score can be assessed on admission and recalculated daily. (A calculator is available at www.sfar.org/scores2/apache22.html.) An APACHE II score higher than 8 indicates severe disease. However, the complexity of the APACHE II score limits its usefulness in the ED setting. An APACHE III score, developed to improve accuracy, does not appear to be more useful than APACHE II in differentiating mild from severe disease.

The “harmless acute pancreatitis score” takes a completely new approach and attempts to predict mild disease instead of severe pancreatitis. This simple clinical algorithm assesses three variables (no rebound tenderness or guarding, normal hematocrit, normal creatinine) to identify patients who have a benign course 98% of the time. This information may quickly aid the physician in determining the appropriate level of care for admission if warranted.

TREATMENT

No specific treatment is available for pancreatitis other than supportive care. Supplemental oxygen, aggressive intravenous hydration, pain management, and monitoring are the mainstays of treatment. Supplemental oxygen is vital for treating and preventing hypoxemia. Aggressive intravenous hydration consists of fluid boluses to establish hemodynamic stability followed by appropriate maintenance fluids is of critical importance in treating and preventing hypovolemia. Hypovolemia occurs secondary to vomiting, decreased oral intake, diaphoresis, third-space losses, and inflammatory-mediated increased vascular permeability. Hypovolemia compromises the pancreatic microcirculation and can contribute to the development of pancreatic necrosis. Nasogastric

*Severity Index Score = Grade score + Percent Necrosis score. Maximum score = 10; severe disease = 6 or higher. †Severity of the acute inflammatory process.
Narcotic analgesia is often needed to control the pain of acute pancreatitis. Controversy exists over which narcotic to use. Morphine has historically been avoided because of the potential to cause spasm of the sphincter of Oddi and subsequent worsening of symptoms. Meperidine is often used in place of morphine, but no conclusive evidence supports the use of meperidine rather than other narcotics. In fact, meperidine has several disadvantages, including the potential formation of neurotoxic metabolites, muscle fibrosis if given intramuscularly, and a short duration of action. Administration of adequate doses of narcotic analgesia is probably more important than the particular narcotic used.

Management of necrotizing pancreatitis usually involves admission to a higher level of care (step-down unit or intensive care unit) because of the associated increased morbidity and mortality. The use of prophylactic antibiotics to prevent infection in patients with pancreatic necrosis is no longer recommended. Antibiotics are indicated for septic patients while an investigation for the source of infection is under taken. Carbapenems are acceptable empiric choices. Infected necrotizing pancreatitis is considered uniformly fatal without intervention and should be suspected in patients with clinical evidence of sepsis. Urgent surgical consultation should be obtained if infection is suspected because aggressive surgical débridement (necrosectomy) may be necessary. CT-guided fine-needle aspiration may be necessary to establish the diagnosis in suspicious cases. Drainage options for patients with pancreatic necrosis who will not undergo surgery (poor surgical candidates or patients whose infection is well contained) are expanding and include both percutaneous therapy (interventional radiology) and endoscopic therapy. Treatment of sterile necrosis remains supportive.

DISPOSITION

Most patients with acute pancreatitis require hospital admission for supportive care and have a benign course. Patients with acute necrotizing pancreatitis usually require admission to either a step-down or intensive care unit for closer monitoring and treatment. The presence of organ failure is one of the indications for considering admission to an intensive care unit. Patients with tachycardia, oliguria, and inadequate pain control may benefit from management in a step-down unit. Mild cases of pancreatitis may be managed on an outpatient basis if the pain is controlled and the patient is tolerating liquids. Patients who are discharged home require proper follow-up and written discharge instructions. Alcoholic patients with pancreatitis are encouraged to stop drinking and seek detoxification treatment.

PANCREAS TRANSPLANT COMPLICATIONS

Acute rejection can occur immediately or at any point during the course of the patient’s life. Patients who have undergone pancreatic transplantation are maintained on immunosuppressive agents and thus are at risk for a variety of infectious complications. Vascular thrombosis of the pancreatic portal vein is a very early complication typically seen within 24 to 48 hours of transplantation and is thought to be due to the relatively low-flow state of the pancreatic graft. Transplantation pancreatitis occurs to some degree in all patients postoperatively within 48 to 96 hours and is usually transient and mild.

Other complications vary with the specific surgical technique performed (i.e., bladder-drained or enteric-drained transplant). Complications of bladder-drained pancreas transplantation include urinary tract infections, hematuria, sterile cystitis, urethritis, balanitis, and metabolic acidosis (because of the bladder excreting large volumes of alkaline pancreatic secretions). Reflux pancreatitis secondary to reflux of urine through the ampulla into the pancreatic ducts can mimic acute rejection but usually resolves after Foley catheterization. The most serious complication of bladder-drained pancreatic transplantation is a urine leak from breakdown of the duodenal segment and is usually seen in the first 2 to 3 weeks postoperatively. A high index of suspicion is required to make the diagnosis because the symptoms usually include nonspecific abdominal pain and elevated pancreatic enzymes. Voiding cystography or CT aids in making the diagnosis. The most serious complication of enteric-drained pancreatic transplantation is leak and intraabdominal abscess, which usually occur 1 to 6 months postoperatively. Patients generally have abdominal pain, fever, and leukocytosis. CT aids in making the diagnosis. Treatment includes broad-spectrum antibiotics and surgical consultation.

TIPS AND TRICKS

The diagnosis of acute pancreatitis should not rely solely on elevations of serum enzymes above the arbitrary limits of normal laboratory levels; instead, it should be based on the onset of clinical symptoms because the sensitivities of these enzyme values change with the timing of their measurements.

Biliary Tract Disorders

Julie J. Cooper

KEY POINTS

- Risk factors for the development of gallstone disease include female gender, increasing age, obesity, rapid weight loss, and underlying liver disease.
- The majority of patients with gallstone disease are asymptomatic. Symptomatic complications include biliary colic, acute cholecystitis, choledocholithiasis, cholangitis, and acute pancreatitis.
- A high index of suspicion should be maintained for acute cholangitis in the chronically ill, elderly, or diabetic patients with sepsis of unknown source.
- Ultrasound is the initial diagnostic study of choice in patients with suspected gallstone disease. Cholecystoscintigraphy is the most sensitive test for cholecystitis, and magnetic resonance cholangiopancreatography is the most sensitive test for bile duct stones.

CHOLELITHIASIS AND ACUTE CHOLECYSTITIS

EPIDEMIOLOGY

Cholelithiasis affects 20 to 25 million Americans, which represents 10% to 15% of the adult population. Although most gallstones are clinically silent, 20% of people harboring stones experience biliary symptoms at some time; 1% to 2% of patients each year experience complications and require surgical removal of the gallbladder. In the United States, cholecystectomy is the most common elective abdominal surgery, with approximately 750,000 procedures performed per year. Complications of cholelithiasis include acute cholecystitis, ascending cholangitis, acute pancreatitis, and adenocarcinoma of the gallbladder, which result in a combined mortality of 5000 to 10,000 deaths per year (Box 44.1).

PATOPHYSIOLOGY

Bile is primarily composed of cholesterol, lecithin, bile salts, bilirubin, and electrolytes (i.e., calcium, carbonate, phosphate). Once these solutes exceed their solubility, they form crystals. Crystals trapped in biliary mucus produce sludge and aggregate to form stones. Cholesterol is the primary constituent in 60% to 80% of all gallstones. Calcium bilirubinate salts predominate in another 10% to 20% of stones; cholesterol and calcium bilirubinate are present in relatively equal quantities in the remainder of calculi. Biliary stasis is thought to play a significant role in stone formation.12

Although bile itself is normally sterile, any alterations in biliary motility lead to an increased risk for bacterial infection. The organisms implicated in cholecystitis are generally bowel flora and include Escherichia coli, Klebsiella, enterococci, and anaerobes.13

PRESENTING SIGNS AND SYMPTOMS

Gallstones can be manifested as a spectrum of disease and may be divided into asymptomatic, symptomatic, and complicated gallstone disease. Only 15% to 20% of stones become symptomatic, between 1% and 3% per year. Approximately 66% of patients have a recurrent episode of biliary colic within 2 years, and about one in six have a complication of gallstone disease13 (Table 44.1).

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Patients with suspected complications of gallstone disease should be evaluated for alternative diagnoses, as well as complications of gallstones such as pancreatitis and cholangitis. Laboratory evaluation for all these patients should include a complete blood count, basic serum chemistries, liver function tests, serum amylase and lipase, and urinalysis. A urine pregnancy test should always be performed in women of childbearing age.

Laboratory test results in patients with symptomatic cholelithiasis should be normal except for a mild elevation in serum alkaline phosphatase. Alkaline phosphatase is synthesized by the biliary tract epithelium but is also found in bone. γ-Glutamyltransferase (GGT) is another enzyme secreted by the biliary epithelium that may be elevated in patients with biliary obstruction.

DIAGNOSTIC IMAGING FOR CHOLELITHIASIS AND CHOLECYSTITIS

Ultrasonography is the preferred first-line modality for evaluating potential biliary stones (Fig. 44.1). A metaanalysis of studies demonstrated that ultrasound has a sensitivity of 97% and specificity of 95% for the diagnosis of cholelithiasis.17 Common findings on ultrasonography are hyperechoic stones, gallbladder wall thickening (>3 mm), common bile duct dilation (>6 mm), and intrahepatic and extrahepatic biliary ductal dilation are highly suggestive of acute cholecystitis.

Cholecystoscintigraphy or hepatobiliary iminodiacetic acid (HIDA) scanning is a more sensitive test for diagnosing acute cholecystitis. In this nuclear medicine study, a radioactive tracer is injected peripherally and allowed to circulate to the liver, where it is excreted in bile. In the absence of disease, the gallbladder is visualized within 1 hour of injection (Fig. 44.4). Nonvisualization of the gallbladder within 4 hours after injection indicates either cholecystitis or cystic duct obstruction.
BOX 44.1 Risk Factors for the Development of Cholelithiasis

Gender
Women have twice the incidence and prevalence of gallstones. Estrogen stimulates low-density lipoprotein receptors and increases the uptake of cholesterol; higher cholesterol content in bile is associated with greater risk for gallstone formation. After menopause, the incidence of gallstone disease in women and men is comparable.

Ethnicity
The incidence of cholelithiasis is highest in North American Indians (especially Pima Indians), followed by South American Indians and Mexican Americans. Black Africans have the lowest incidence and prevalence of gallstone disease.

Age
Gallstone prevalence increases after 40 years of age.

Obesity
Obesity is associated with increased cholesterol secretion into bile.

Rapid Weight Loss
Low-calorie diets and rapid weight loss are associated with the development of gallstones in 30% to 71% of persons. Weight loss exceeding 1.5 kg/wk, after bariatric surgery in particular, increases the risk for stone formation.

Total Parenteral Nutrition
Loss of enteric stimulation of the gallbladder in the absence of eating leads to gallbladder stasis. Total parental nutrition (TPN) increases the risk for biliary sludge, gallstone disease, and acalculous cholecystitis. After 4 weeks of TPN, gallbladder sludge develops in half of patients and after 6 weeks in all. The sludge resolves within 4 weeks of resuming oral intake.

Family History
Occurrence of gallstone disease within families can be a product of genetic and shared environmental factors. The frequency is increased in monozygotic (12%) as opposed to dizygotic twins (6%). Genetic effects account for 25%, shared environmental effects for 13%, and unique environmental effects for 62% of the phenotypic variance in gallstone production.

Chronic Diseases
The overall prevalence of gallstones in patients with cirrhosis is 25% to 30% (double that in the general population). Crohn disease causes ileal malabsorption of bile acids. These acids normally solubilize cholesterol and bilirubin to be excreted. An inadequate amount of bile acid means that increased cholesterol and bilirubin are available to form stones. Cystic fibrosis is also associated with bile acid malabsorption and gallstones.

Medications
Octreotide is used for the treatment of acromegaly and carcinoid syndrome; it affects biliary motility and sphincter of Oddi function. Cholelithiasis develops in more than 50% of patients receiving octreotide. The majority are asymptomatic. Ceftriaxone is secreted unmetabolized into bile, where it reaches high concentrations and produces biliary sludge.

Fig. 44.2 Cholelithiasis shown by ultrasonography (arrows). G, Gallbladder. (From Berk RN, Ferrucci Jr JT, Leopold GR. Radiology of the gallbladder and bile ducts: diagnosis and intervention. Philadelphia: Saunders; 1983. p. 255.)

Fig. 44.3 Ultrasonogram demonstrating pericholecystic fluid (arrow). G, Gallbladder. (From Berk RN, Ferrucci Jr JT, Leopold GR. Radiology of the gallbladder and bile ducts: diagnosis and intervention. Philadelphia: Saunders; 1983. p. 213.)

In a retrospective review of 170 patients evaluated in the emergency department (ED) because of right upper quadrant (RUQ) pain, cholecystoscintigraphy had a diagnostic sensitivity of 86% for acute cholecystitis as compared with 48% for ultrasonography. In another study, the results of cholecystoscintigraphy were positive in 87% of patients in whom the initial ultrasonographic findings were negative.18

Computed tomography (CT) is less sensitive than ultrasonography for the diagnosis of acute biliary disease.19 CT may offer valuable information about the surrounding anatomy if confounding clinical signs or symptoms are present, if ultrasonography does not demonstrate calculi, or if an alternative diagnosis is as likely as biliary disease (Fig. 44.6). A retrospective study of 123 patients who underwent both CT and RUQ ultrasonography demonstrated a sensitivity of only 39% for CT in detecting biliary disease.19 Ultrasonography had a sensitivity of 83% in that study and suggested the correct diagnosis in seven of eight patients in whom the CT findings led to misdiagnosis (Fig. 44.7). Figure 44.8 presents a summary of the diagnostic and treatment algorithm for right upper quadrant pain.

**TREATMENT**

**MEDICAL MANAGEMENT**

Initial ED management of all patients with suspected complications of gallstone disease should include nothing by mouth, intravenous fluids, analgesics, and antiemetics as needed. For those without contraindications to nonsteroidal antiinflammatory drugs (NSAIDs), ketorolac (Toradol), 60 mg intramuscularly (IM) or 30 mg intravenously (IV), is an effective parenteral treatment of biliary colic. Opiate analgesia starting at 0.1 mg/kg of morphine or its equivalent is appropriate for patients in whom NSAIDs do not provide adequate effect. Nausea and vomiting are treated with metoclopramide (Reglan), 10 mg IV, or ondansetron (Zofran), 4 mg as an orally disintegrating tablet, IM, or IV.

Empiric antibiotics should cover *E. coli*, *Klebsiella*, *Streptococcus faecalis*, and anaerobic organisms. An acceptable combination regimen consists of a third- or fourth-generation cephalosporin (e.g., ceftazidime) plus metronidazole. An alternative would be a combination of a β-lactam antibiotic and a β-lactamase inhibitor such as piperacillin and tazobactam or ampicillin and sulbactam.13

Medical therapy for chronic gallstone disease may include oral bile acids or extracorporeal shock wave lithotripsy (ESWL). Oral bile acids dissolve cholesterol gallstones. The most commonly used agent is ursodeoxycholic acid, which is a primary bile acid of bears. It both dissolves cholesterol gallstones and reduces biliary cholesterol secretion.20 ESWL fragments gallstones with external shock waves. These stones are then more amenable to dissolution with oral bile acids. The major complications are biliary colic and problems stemming from the expulsion of smaller gallstones, such as acute pancreatitis.21

CHAPTER 44  BILIARY TRACT DISORDERS

SURGICAL MANAGEMENT

Laparoscopic cholecystectomy is the mainstay of surgical treatment of symptomatic gallstones. When compared with open cholecystectomy, laparoscopic surgery is associated with decreased postoperative pain; decreased hospital length of stay; decreased risk for mortality, cardiopulmonary complications, and wound infections, but also with an increased risk for bile duct injuries.22,23 Cholecystectomy is also the treatment of choice for acute cholecystitis. Although the timing of surgery in this context has been debated, early cholecystectomy within a few days of initial evaluation is probably associated with lower morbidity and mortality.24 Patients who are critically ill or have acute contraindications to cholecystectomy can be temporized with percutaneous cholecystostomy for drainage pending definitive management.

The most common immediate complication of cholecystectomy is bile leakage, which is treated by endoscopic retrograde cholangiopancreatography (ERCP) with stent placement.25 Stent placement decreases outflow resistance and allows spontaneous closure of the leak, usually within a few days. Postoperative cholecystectomy patients with recurrent abdominal symptoms should be evaluated for retained stones along with choledocholithiasis, pancreatitis, abscess, or bile leak.

Fig. 44.6  A to D, Computed tomography scans showing cholelithiasis (arrows and arrowheads) in four different patients. (From Berk RN, Ferruci Jr JT, Leopold GR. Radiology of the gallbladder and bile ducts: diagnosis and intervention. Philadelphia: Saunders; 1983. p. 215.)

Biliary Colic
Avoid high-fat foods.
Use prescribed pain and nausea medications as needed.
Return to the emergency department if you have intractable pain, vomiting, fever, or chills.
Make a follow-up appointment with a surgeon.

PATIENT TEACHING TIPS

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients with biliary colic may be discharged home if their symptoms can be adequately controlled with oral medications, complications have been excluded with blood tests and appropriate imaging, and they are able to arrange follow-up with a surgeon. Patients should be discharged with an adequate supply of analgesic and antiemetic medications and strict return precautions for intractable pain or vomiting, fever, or jaundice. Those with suspected cholecystitis should be admitted to the hospital for intravenous antibiotics and definitive imaging studies with surgical consultation.

Table: DOCUMENTATION

- Presence of fever, changes in stool color, vomiting
- Personal or family history of gallstones
- Presence of the Murphy sign or jaundice on physical examination
- Improvement in pain, tolerance of oral fluids, and patient teaching before discharge
- Return precautions, referral to a surgeon
**CHOLEDOCHOLITHIASIS AND CHOLANGITIS**

**Epidemiology**

Approximately 80% of cases of cholangitis are caused by obstructing gallbladder stones, with a reported mortality of 5%.26

**Pathophysiology**

*E. coli, Klebsiella, Streptococcus, Clostridium,* and *Bacteroides* are the common bacterial organisms inciting cholangitis. Infection usually spreads in a retrograde fashion from the intestines because of obstruction. The resulting damage to the biliary ductal epithelium causes fibrosis and ductal loss. This sequence of events may also be seen without biliary obstruction in patients who have undergone sphincteroplasty or biliary anastomosis to the duodenum (sump syndrome).15

Infection by the Chinese liver fluke (*Clonorchis sinensis*) with secondary bacterial infection can cause cholangitis. Patients with acquired immunodeficiency syndrome may have cholangitis with or without obstruction. The infectious organisms associated with this and other immunodeficiency disorders are cytomegalovirus, *Cryptosporidium, Cryptococcus,* and *Candida albicans.*27,28 Neonates may have cholangitis secondary to cytomegalovirus or reovirus type III. Cholangitis may also be seen in patients with failing liver transplants as a result of graft incompatibility or hepatic arterial thrombosis.29 Rejection leading to cholangitis is likewise seen in patients who have undergone allogeneic bone marrow
transplantation. Progressive biliary ductal necrosis eventually leads to cirrhosis (Table 44.2).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis of choledocholithiasis and cholangitis encompasses the previously discussed differential diagnosis of RUQ pain and gallstone disease.

Laboratory evaluation may help distinguish biliary colic and cholecystitis from choledocholithiasis. In choledocholithiasis, more than 90% of patients will have elevations in serum alkaline phosphatase and GGT levels. Obstruction of the common bile duct will lead to elevation of total and conjugated serum bilirubin, although most ductal stones result in serum bilirubin levels lower than 15 mg/dL because the biliary obstruction that they cause is intermittent. Serum transaminase levels may be elevated, rarely with profound elevations of greater than 2000 IU/L mimicking acute hepatitis.

Transabdominal ultrasound has low sensitivity (25% to 60%) for the detection of bile duct stones, but it has a very high specificity. Stones within the common bile duct are difficult to visualize on ultrasonography, but greater than 6-mm dilation of the common bile duct suggests the presence of a calculus. CT imaging also has low sensitivity for bile duct stones but can demonstrate biliary dilation and exclude other causes of biliary obstruction such as tumor. Magnetic resonance cholangiopancreatography and ERCP can detect stones with comparable accuracy (Fig. 44.9).

**TREATMENT**

Initial management of cholangitis is typically medical with empiric antibiotics. Multiple antibiotic regimens are acceptable, and emergency physicians should follow institutional preferences and local resistance patterns when choosing antibiotics. Accepted regimens are combination therapy with an extended-spectrum cephalosporin, metronidazole, and ampicillin; single-agent or combination fluoroquinolones; and ureidopenicillins alone or with metronidazole. Although fluoroquinolones are thought to have greater biliary penetration, they do not change the mortality associated with this disease. Unless concomitant signs of infection are present, patients with primary sclerosing cholangitis do not experience improvement with antibiotics.

ERCP with sphincterotomy is the treatment with the lowest mortality. Percutaneous transhepatic cholangiography (PTC) with drainage is a consideration for patients in whom ERCP fails. Emergency common bile duct exploration with T-tube placement can be performed either by open means or laparoscopically. If emergency ERCP or PTC cannot be arranged in the ED, surgical consultation should be obtained.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with infectious cholangitis should be admitted to the hospital for biliary drainage in consultation with gastroenterology or surgery (or both).

RUQ, Right upper quadrant.
TUMORS OF THE BILIARY TREE AND GALLBLADDER

EPIDEMIOLOGY

Tumors of the biliary tree are relatively rare and range from benign tumors such as adenoma and papilloma to carcinoma of the gallbladder and cholangiocarcinoma. Because gallbladder carcinoma is closely associated with underlying gallbladder disease and chronic stasis, patient populations at risk for gallstone disease are also at higher risk for gallbladder carcinoma (see Box 44.1). The overall 5-year survival rate in patients with gallbladder cancer is approximately 12%.

PATHOPHYSIOLOGY

Papillomas and adenomas are benign tumors of the gallbladder. Papillomas are small, usually multiple tumors that contain cholesterol esters and are not precancerous lesions. Adenomas, semisolid masses found at the fundus, are normally solitary. Both tumors are asymptomatic and can be distinguished from gallstones ultrasonographically because of their fixed position with movement of the patient.

Carcinoma of the gallbladder is an uncommon malignancy associated with chronic cholecystitis and porcelain gallbladder (Fig. 44.10). It is most commonly an adenocarcinoma that arises in the fundus or neck. Physical examination usually demonstrates jaundice in an elderly patient, RUQ pain, and weight loss. An abdominal mass may be palpable.

Cholangiocarcinoma refers to malignancy anywhere from the intrahepatic ducts to the common bile duct. It is an adenocarcinoma that spreads along and through the duct wall, with extension to the lymph nodes, peritoneum, gallbladder, and liver in 50% of patients. Associations with primary biliary cirrhosis (PBC), primary sclerosing cholangitis, ulcerative colitis, and C. sinensis infestation have been documented. One study found that the risk for bile duct carcinoma significantly decreases 10 years after cholecystectomy.

PRESENTING SIGNS AND SYMPTOMS

Patients are most commonly seen in the ED with painless jaundice and pruritus, symptoms that suggest an obstructing mass in the distal biliary tree. Pain is present in only one third of patients and is generally mild. Those with malignancy have associated malaise and weight loss. Hepatomegaly without splenomegaly is often noted. Fever is uncommon, but if present, concurrent cholangitis should be considered.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

A thorough search for the cause of jaundice in an older patient should be initiated in the ED and will likely necessitate admission for further imaging studies. Liver function tests show elevations in serum bilirubin and alkaline phosphatase.

Ultrasonography and CT demonstrate intrahepatic biliary ductal dilation in jaundiced patients but may not show the actual mass. Depending on the tumor’s location along the biliary tree, the common duct may be normal or may be dilated proximal to the mass.

Both ultrasonography and CT have a sensitivity of 60% to 70% for detecting carcinoma; when results are positive, they usually show a mass in the lumen. Spread via the venous and
lymphatic systems prevents early detection, and metastasis is present at the time of diagnosis in 50% of cases. The 1-year survival rate after diagnosis is approximately 14%.

**TREATMENT**

Treatment of cancers of the biliary tree depends on the subtype of tumor and the extent of spread. Any combination of surgery, chemotherapy, and radiation therapy may be indicated.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with jaundice and findings suspicious for a tumor should be admitted to a medical service for ERCP and biopsy.

**PRIMARY BILIARY CIRRHOSIS**

**EPIEDEMOLOGY**

PBC progressively destroys the intrahepatic bile ducts (Fig. 44.11). The disease is found in all races, with a 90% female preponderance. PBC is diagnosed in patients 20 to 80 years of age, although the majority of cases are found in patients 40 to 60 years old. A genetic predisposition is likely because family members of patients with PBC have a higher prevalence of mitochondrial antibodies associated with the disease. A medical history of an autoimmune disorder such as rheumatoid arthritis, systemic lupus erythematosus, or mixed connective tissue disease has an association with PBC.

**PATHOPHYSIOLOGY**

The etiology of this disease is unknown, but the final mechanism involves immune-mediated biliary duct destruction via cytotoxic T cells. Viruses, bacteria, and defective immune regulation have been theorized to incite this cascade.

**PRESENTING SIGNS AND SYMPTOMS**

Patients are normally asymptomatic but may experience pruritus. Chronic RUQ pain is an infrequent complaint, and jaundice is not an early feature of this disease. Patients may remain asymptomatic for many years after ductal destruction has begun, but for those with symptoms and jaundice, the average survival time without treatment is 7 years.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The most common laboratory abnormality is an elevation in serum alkaline phosphatase and GGT. Total serum cholesterol is usually elevated and the serum bilirubin value only mildly elevated (generally less than 2 mg/dL). Complications of the disease result from liver cirrhosis (i.e., ascites, bleeding esophageal varices, coagulopathy). The diagnosis is suggested by antimitochondrial antibodies in the serum and confirmed by liver biopsy.

**TREATMENT**

Treatment is initially aimed at controlling itching and steatorrhea. Vitamin D and calcium supplements are necessary because of the bile deficiency. The only drug shown to improve mortality in patients with PBC is ursodeoxycholic acid. Hepatic transplantation is the best treatment option to extend life, with a 5-year survival rate of 60% to 70%.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with cirrhotic complications should be considered for transplantation. Those in whom complications are diagnosed early or who have a serum total bilirubin value of 9 mg/dL or higher should be transferred to a transplant center.

INTRODUCTION

Hepatobiliary disease is a common cause of abdominal pain in patients evaluated in the emergency department. Cholelithiasis is present in 20 to 25 million of Americans, which represents 10% to 15% of the adult population. Cholecystectomy has become the most common elective abdominal surgery performed in the United States. Significant clinical symptoms, however, do not develop in the majority of patients (up to 80%) with gallstones. Both the prevalence and the complication rate of cholelithiasis increase with age. Biliary infection is a common cause of abdominal sepsis in the elderly.

Ultrasound is the initial imaging modality most commonly used for hepatobiliary evaluation in cases of suspected cholecystitis and biliary obstruction. Timely comprehensive sonographic evaluation is not always available in the emergency setting, and an increasing number of emergency providers use point-of-care biliary sonography to rapidly evaluate symptomatic patients for the presence of cholelithiasis and its complications.

Evaluation of elderly patients with suspected biliary sepsis is frequently complicated by altered mental status. In contrast to younger patients, sepsis from ascending cholangitis may be accompanied by atypical or vague clinical findings. Focused ultrasound is a valuable tool that can quickly evaluate the hepatobiliary tract and expedite appropriate treatment and disposition when signs of biliary infection are found.

Bedside ultrasound is also a useful adjunct to the emergency physician for certain patients with chronic hepatic disease. Ultrasound can quickly evaluate for the presence of ascites and provide procedural guidance for paracentesis.

KEY POINTS

- Hepatobiliary disease has a high prevalence and is a common cause of abdominal symptoms in patients seeking care in the emergency department.
- Biliary infections represent up to 25% of the causes of intraabdominal sepsis in the elderly.
- Poor sensitivity of the clinical and laboratory data for cholecystitis creates a large demand for hepatobiliary imaging.
- Ultrasound is the initial imaging modality of choice in evaluating the biliary tract for suspected infection or obstruction.
- Focused hepatobiliary ultrasound is a skill that can be effectively learned by emergency department physicians and performed rapidly at the patient’s bedside.
- Focused hepatobiliary ultrasound is a dynamic process that can be facilitated by proper patient positioning, inspiratory maneuvers, and Doppler evaluation.
- Bedside ultrasound is a useful adjunct for the detection of ascites in patients with hepatic disease and can provide procedural guidance for paracentesis.

REVIEW OF LITERATURE ON EVALUATION FOR CHOLECYSTITIS

Clinical findings and laboratory data lack acceptable sensitivity to rule out cholecystitis, which has led to the need for abdominal imaging to aid in determining the patient’s disposition. Commonly used imaging modalities to evaluate for cholecystitis and its complications are ultrasound, computed tomography (CT), and cholescintigraphy or hepatobiliary iminodiacetic acid (HIDA) scanning. The sensitivity and specificity of ultrasound for the detection of cholelithiasis can approach 100% for providers with significant ultrasound experience. CT is much less sensitive than ultrasound for detecting cholelithiasis and misses up to 25% of gallstones. HIDA scanning has been reported to have high sensitivity for acute cholecystitis, but it does not provide an adequate structural evaluation of the hepatobiliary system. HIDA scanning also has limited availability in many locations and is not a practical screening modality in the emergency department setting. These distinctions make ultrasound the imaging modality of choice for the initial evaluation of patients with right upper quadrant pain and suspected cholecystitis.

Emergency physicians have demonstrated the ability to effectively learn to perform point-of-care bedside hepatobiliary ultrasonography. Studies on emergency physician–performed biliary sonography have demonstrated sensitivities and specificities of up to 92% and 87% for the detection of cholelithiasis.
BILIARY DUCT EVALUATION

Transabdominal ultrasound is the initial imaging modality used to evaluate for suspected choledocholithiasis and obstruction of the biliary ducts. In the western world, gallstones are the most common cause of both biliary obstruction and cholangitis.\textsuperscript{11,12} Even with the most advanced equipment, the sensitivity of ultrasound in detecting choledocholithiasis is still essentially dependent on the examiner’s proficiency and can range between 22% and 100%.\textsuperscript{5,11,13-15} Specific data on the accuracy of emergency medicine physicians’ performance in detecting choledocholithiasis are not yet available and need further investigation. The overall specificity of transabdominal sonography for detection of common bile duct (CBD) stones is usually very high and ranges between 95% and 100%.\textsuperscript{11}

PATIENT POSITIONING

Imaging begins with the patient in a supine position, but it should be acknowledged that repositioning the patient is required in many cases to obtain the views needed. Rolling the patient to the left lateral decubitus position can help displace the bowel and reduce interference from bowel gas. In some cases, rolling a patient to a semi-prone position or having the patient stand up may further facilitate image acquisition. If possible, the patient should elevate the right arm above the head to improve the sonographic accessibility of the inferior liver and for transthoracic scanning.

INSPIRATORY TECHNIQUES

Having patients hold their breath after a full inspiration is also a useful technique. This pushes the liver inferiorly and may aid in displacing the overlying bowel. The liver also provides a friendly imaging window. However, breath-holding can increase air in the antrum, pylorus, and duodenum, which can interfere with the ability to visualize the gallbladder. In general, in the beginning of the examination it is often better to place the probe over the anatomic area of interest and review structures of interest as they are pushed in and out of the sonographic field via the normal respiratory cycle. Once the patient initiates breath-holding, air swallowed into the antrum will quickly move with peristalsis and may obscure areas of interest.

SYSTEMATIC SCANNING APPROACH

Significant anatomic variability, interference from adjacent bowel, and variations in the amount or overlying tissue can make localization of the gallbladder a difficult task. Gallbladder imaging is best approached as a dynamic process, and the sonographer should be prepared to try different imaging windows and repositioning of the patient as needed to obtain the appropriate images.

The authors suggest the following systematic approach:

1. The patient is placed in a supine position with the right arm raised above the head. To begin the examination, the patient is placed in a supine position with the right arm raised above the head. To begin the examination, the
sonographer should imagine a line that connects the patient’s umbilicus and right shoulder. The probe is placed immediately below the intersection of this line with the right inferior costal margin. The probe is placed parallel to the rib in about 45 degrees of angulation (see Fig. 45.1).

2. If the liver and aspects of the gallbladder are not in the visual field, the probe is fanned cephalad and caudal. If the gallbladder is still not visualized, the probe should be moved slowly along the inferior costal margin while repeating the fanning motion upward and downward and moving the probe laterally and medially.

3. If no liver tissue or gallbladder can be visualized along this inferior margin, the probe is moved one intercostal space up and placed in the same position where the line between the umbilicus and right shoulder intersects with now the last intercostal space. The probe is angled 60 to 90 degrees (Fig. 45.2). Next, the fanning maneuver is repeated and the probe moved within this intercostal space medially and laterally. The process is repeated in next intercostal space if needed.

4. If unsuccessful, the transducer is placed in a modified focused abdominal sonography for trauma (FAST) view. Instead of angling down to the retroperitoneal location of the kidney, the transducer is angled up toward the tip of the liver, and the lateral margin of the liver is scanned until the gallbladder is located.

5. If unsuccessful after steps 1 to 4, the patient is placed in the left lateral decubitus position and steps 1 to 4 are repeated.

6. Finally, if feasible, have the patient stand up, which often drops the liver and gallbladder more caudally and makes them more accessible for sonography.

GALLBLADDER EVALUATION

After locating the gallbladder, the probe is rotated clockwise and counterclockwise as needed to obtain a longitudinal (long-axis) view (Fig. 45.3). Next, the probe is moved medially and laterally to evaluate the entire gallbladder in long axis. A normal gallbladder has echogenic walls with an anechoic internal cavity. The gallbladder should be thoroughly evaluated for the presence or absence of cholelithiasis. Special attention should be paid to the gallbladder neck for impacted stones.

Following long-axis evaluation, the probe is rotated 90 degrees to the patient’s right (the indicator is rotated 90 degrees counterclockwise), which will give a transverse or short-axis view of the gallbladder (see Fig. 45.3). The probe should be angled or moved cephalad and caudal to evaluate the entire gallbladder. The gallbladder is scanned from the fundus to the neck. Again, particular attention should be directed to the gallbladder neck. Air artifact can obscure small stones in this area.

The next step should be to measure the thickness of the gallbladder wall (Fig. 45.4). Transmission of ultrasound waves through the fluid-filled gallbladder leads to enhancement of the posterior gallbladder wall, and posterior enhancement can result in overestimation of wall thickness. Hence, measurements are obtained at the anterior wall. Thickness of the anterior wall greater than 3 mm is considered abnormal. One should be aware that isolated increased gallbladder wall thickness is not a sensitive finding for detecting acute inflammation because it can be caused by multiple disease processes (e.g., chronic cholecystitis, ascites, hepatitis). Next, the area encompassing the gallbladder should be evaluated for the
presence of pericholecystic fluid. This finding will appear as anechoic areas adjacent to the gallbladder. Pericholecystic fluid with septations, internal echoes, or thick walls may suggest perforation of the gallbladder with abscess formation.18

Finally, one should evaluate for a sonographic Murphy sign, which is defined as reproducible tenderness when transducer pressure is applied with the gallbladder in direct view. Correct evaluation for the Murphy sign includes repeating this maneuver on both the left and right sides next to the gallbladder, but with the gallbladder out of the visual field. With a true Murphy sign, tenderness or discomfort in areas away from the gallbladder should be significantly less.18

COMMON BILE DUCT
Locating the Common Bile Duct
The CBD is approximately 4 cm long and intimately associated with the portal vein and hepatic artery in the portal triad. Several approaches can be used to locate this structure. First, one can attempt to find the portal triad. The CBD is located ventral to the portal vein and lacks flow with Doppler imaging. One method to locate the portal triad is to follow the intrahepatic portal vein branches to the liver hilum and main portal vein. The CBD can also be found when following the neck of the gallbladder or the main lobar hepatic fissure toward the hepatic hilum. If the proximal portion of the CBD is difficult to assess, the distal part can be located when scanning the pancreatic head and the duct can then be traced back along the portal vein.

Evaluation of the Common Bile Duct
Once located, the sonographer should interrogate the portal triad with color Doppler to distinguish the CBD from the vessels. The hepatic artery and the portal vein should demonstrate flow, whereas the CBD will not (Fig. 45.5). In patients with sluggish portal flow, the sensitivity of the color or power Doppler settings should be adjusted until the vessels can be distinguished from the CBD. This should be carefully evaluated with a steady hand because motion artifact may produce the illusion of flow with more sensitive Doppler settings. Once the CBD is identified, it should be measured inner wall to inner wall in the transverse plane (Fig. 45.6).

CBD diameter sizes of 1 mm per decade of life and CBD measurements of up to 1 cm following cholecystectomy have traditionally been accepted as normal.20 Measurements of CBD diameter accepted as normal range from 6 to 8 mm, with 7 mm commonly recognized as the upper limit of normal CBD size.21,22

More recent studies, however, do not correlate with the extent of traditionally expected increases in size in elderly and postcholecystectomy patients. A large study of patients older than 60 years found that mean bile duct size increases from

Fig. 45.4 Measuring gallbladder wall thickness. Wall thickness is measured at the anterior wall of the gallbladder in transverse (preferred, A) or longitudinal (B) view.

Fig. 45.5 Common bile duct (CBD) in transverse view (A) showing no flow with Doppler (B, white arrow).
**SECTION IV**  ❯ GASTROINTESTINAL DISEASES

**Fig. 45.6** A, Common bile duct (CBD) measurement is performed from inside to inside wall. B, Using the zoom-in function can be helpful to visualize small CBDs (arrow).

**Fig. 45.7** Main lobar fissure. The main lobar fissure (arrow) is an echogenic, fibrous structure that can be used as a landmark to connect the gallbladder to the portal triad. The portal triad is seen in transverse view with the portal vein (blue circle), hepatic artery (red circle), and common biliary duct (green circle).

3.6 ± 0.26 mm at 60 years of age to 4 ± 0.25 mm in patients older than 85. Interestingly, 98% of ducts were less than 7 mm in diameter. Additionally, two large studies of patients undergoing cholecystectomy revealed postsurgical mean CBD diameters of 3.96 mm and 6.1 mm, respectively.

**MAIN LOBAR FISSURE**

The gallbladder and the hepatic hilum are connected by the hepatic main lobar fissure (Fig. 45.7). Sonographically, it appears as a bright echogenic structure, relative to the adjacent liver, because of its fibrous content. It is a useful landmark that can be followed away from the gallbladder to locate the portal triad. Conversely, it can be traced from the portal triad to locate obscure gallbladders.

**COMMON OBSTACLES AND TIPS**

**Obesity**

Obesity often increases the depth needed to reach the structures of interest, which decreases the quality of the images. For obese patients, one should consider using a lower-frequency probe or changing to lower-frequency settings to increase tissue penetration.

**Bowel Gas**

The acoustic mismatch that occurs when bowel gas is encountered creates artifacts that prevent the user from visualizing distal structures. If bowel gas interferes with the sagittal imaging technique mentioned earlier, the transducer can be moved laterally to a near-coronal or coronal imaging plane (step 4 above). From this location, the liver can be used as an acoustic window to locate the gallbladder. Imaging from a coronal plane may be complicated by interference from rib shadowing. Having the patient take several sips of water, if possible, may also help displace gas in the small bowel within the upper gastrointestinal tract. After waiting 15 to 30 minutes, peristalsis may create changes in the bowel gas and better imaging windows may be found.

**Postprandial Patients**

Postprandial patients typically have a contracted gallbladder, which makes evaluation of wall thickness unreliable (Fig. 45.8). Contracted gallbladders can also be more difficult to locate.

**IMAGES—NORMAL AND ABNORMAL**

**CHOLELITHIASIS**

Gallstones tend to be rounded, mobile structures found in a dependent position. They have a highly reflective surface, which leads to visualization of a curved echogenic surface and shadowing posterior to the gallstone (Fig. 45.9). An attempt should be made to confirm that the gallstones identified are mobile and not impacted.

**ACUTE CHOLECYSTITIS**

Components of the focused sonographic examination for suspected cholecystitis are listed in Box 45.1. Because no single sonographic finding is diagnostic of cholecystitis, the ultrasound findings must be interpreted in conjunction with the clinical picture and laboratory data. The absence of cholelithiasis combined with a negative sonographic Murphy sign has a negative predictive value of 95%. When cholelithiasis is identified, its positive predictive value is increased in the
presence of gallbladder wall thickening (95%) or a positive sonographic Murphy sign (92.2%).26 Pericholecystic fluid is also a common finding in patients with acute cholecystitis (Fig. 45.10).

**Cholecystitis Variants**

Emphysematous cholecystitis occurs when the gallbladder is infected with a gas-producing organism. Focal areas of gas and its characteristic appearance of small, hyperechoic areas with reverberation artifacts can be identified within the gallbladder wall (Fig. 45.11). This can be difficult to differentiate from overlying bowel in some cases. Less than 10% of cases

---

**BOX 45.1 Components of Focused Hepatobiliary Sonography for Suspected Cholecystitis**

- Evaluate for cholelithiasis
- Measure the anterior gallbladder wall
- Measure the common bile duct
- Evaluate for pericholecystic fluid
- Evaluate for a sonographic Murphy sign
Dilation of the intrahepatic biliary ducts (Fig. 45.15) suggests ductal obstruction, although it is not diagnostic of a specific etiology. Obstruction has multiple causes, including choledocholithiasis (most common in the western world; Fig. 45.16), biliary duct stricture, ductal edema (as seen with Mirizzi syndrome), and compression from pancreatic masses.

When dilation of the CBD is found, the duct should be followed as far medially as possible to search for choledocholithiasis. Scanning through the liver may also reveal intrahepatic ductal dilation. Sensitivity is significantly dependent on operator performance and ranges from 25% to 100%.5

Cholangitis
Cholangitis is due to a combination of infection and complete or partial biliary obstruction. Choledocholithiasis is the most common cause. Focused ultrasound is a sensitive modality for detection of choledolithiasis and biliary ductal dilation. Identification of these findings should be correlated to the clinical picture. Biliary ductal dilation is not specific for choledocholithiasis and cholangitis, and ultrasound lacks universal high sensitivity for detecting choledocholithiasis, the main cause of cholangitis.

Liver Masses
Although use of ultrasound for evaluation of liver masses is beyond the scope of emergency medicine, observation of liver masses with bedside imaging is not uncommon. Common benign liver masses are hemangiomas (Fig. 45.17) and adenomas. Metastatic disease is the most frequent cause of malignant liver masses, and hepatocellular carcinoma is the most common primary malignant liver tumor. The sonographic features of hepatic masses depend on both the composition of the liver mass and secondary factors, such as associated edema, hemorrhage, and necrosis. The findings often mimic a target lesion (Fig. 45.18).

Identification of a liver mass should prompt appropriate referral for further work-up. Liver cysts can also be encountered, and the findings can be quite impressive in patients with polycystic liver disease, which is often combined with kidney disease (Fig. 45.19).
Fig. 45.12  Acalculous cholecystitis. This patient arrived at the emergency department with a history of pneumonia and a lung abscess with severe sepsis. Abdominal ultrasound showed significant gallbladder wall edema and thickening. No gallstones were found in this patient. Transverse (A) and longitudinal (B) views of the gallbladder are shown.

Fig. 45.13  Gallbladder abscess. This patient had marked abdominal pain and fever for several days. Ultrasound in the emergency department showed an irregular, complex fluid collection with internal septations adjacent to the gallbladder (arrows).

Fig. 45.14  WES sign. The WES sign stands for “wall-echo-shadow.” The echogenic gallbladder wall (W) is followed by a trace amount of biliary fluid and then by a curved, echogenic surface of a large gallstone (E) followed by posterior shadowing (S). In some cases the intervening biliary fluid may not be appreciated.

HEPATITIS AND CIRRHOSIS
The most common sonographic features of acute hepatitis are increased liver size and decreased echogenicity of the liver (because of increased fluid content as a result of inflammation and edema).

Chronic liver disease and other conditions that elevate portal venous pressure can produce sonographic findings that can mimic acute cholecystitis. Gallbladder wall thickening and ascites are common findings. Ascites may be mistaken for pericholecystic fluid. As the disease progresses, the liver will eventually become hyperechoic in comparison with healthy liver tissue with tissue changes manifested as multiple liver nodules surrounded by echogenic fibrotic tissue. As the cirrhosis progresses, the liver typically decreases in size. Occasionally, a transjugular intrahepatic portosystemic shunt can be detected in patients with portal hypertension (Fig. 45.20).

NORMAL VARIANTS
Polyps appear sonographically as fixed, pedunculated structures adherent to the gallbladder wall that are unchanged by patient positioning. Gallstones are typically mobile and settle to dependent areas of the gallbladder cavity unless they are impacted. Gallbladder polyps do not normally cause posterior shadowing (Fig. 45.21). Gallbladder folds are commonly encountered normal variants that appear as a bright echogenic line within the gallbladder lumen. A fold at the fundus is commonly seen and is termed a phrygian cap (Fig. 45.22). A fold may appear to divide the gallbladder into two sections.
Fig. 45.15  Appearance of intrahepatic biliary duct dilation. A–D, Multiple areas of intrahepatic ductal dilation (arrows) can be seen. Intrahepatic biliary ducts have echogenic walls and typically contain anechoic bile within. Color Doppler can be used to differentiate bile ducts (no flow) from vessels (see Fig. 45.16). Prominent dilation of major biliary ducts is sometimes described as a “staghorn” appearance (C).

Fig. 45.16  Common bile duct dilation and choledocholithiasis. A, Semilongitudinal view of a dilated common bile duct (CBD) (measured at 9.4 mm; stars indicate the ends of the calipers measuring the common bile duct) Long axis (B) and short axis (D) of the dilated proximal CBD. The portal triad consisting of the portal vein (blue circle), hepatic artery (red circle), and dilated common biliary duct (green circle) is seen in D in transverse view. C, Color Doppler image of the distal CBD (no internal flow is seen) with a large stone and posterior shadowing (asterisk).
Careful imaging of the gallbladder in multiple planes can decrease the likelihood of misdiagnosis.

Adenomyomatosis is a common benign condition with a reported incidence of 2.8% to 5% that leads to hyperplastic changes and thickening of the gallbladder wall. It is usually asymptomatic, however. In the majority of cases it is associated with chronic biliary inflammation, most commonly gallstones in 25% to 75% but also cholecystitis in 33% and pancreatitis. Cholesterol crystals precipitate in the bile trapped in Rokitansky-Aschoff sinuses and cause a quite a distinct sonographic ring-down artifact (Fig. 45.23). Duplicated gallbladder, intrahepatic gallbladder, and congenital absence of the gallbladder are all uncommon variants that may be encountered.

**GALLBLADDER SLUDGE AND GRAVEL**

Gravel is a variant of cholelithiasis that has a distinct ultrasound appearance identified as multiple small individual dependent stones (Fig. 45.24). Sludge produces a homogeneous, hyperechoic area in the gallbladder that does not produce shadowing. Sludge is viscous and settles to the dependent portion of the gallbladder, but it may take longer to settle than larger stones (Fig. 45.25).

**HOW TO INCORPORATE EVALUATION OF SUSPECTED CHOLECYSTITIS INTO PRACTICE**

Findings should be correlated with the clinical and laboratory picture. The absence of cholelithiasis on focused hepatobiliary imaging makes the diagnosis of cholecystitis much less
likely, and other diagnoses should be entertained. Patients with ultrasound findings suggestive of cholecystitis should be administered antibiotics and undergo surgical consultation. If cholelithiasis is seen without other evidence of cholecystitis, the patient’s laboratory findings and clinical picture should be reviewed. Patients with resolution of pain and without laboratory abnormalities should have close follow-up arranged. Patients with persistent pain or laboratory abnormalities concerning for cholecystitis should undergo appropriate consultation and possibly a HIDA scan.

**BILIARY SEPSIS**

Biliary infection is a common cause of sepsis, and its incidence increases with age. Findings on bedside ultrasound, when suggestive of cholecystitis or cholangitis, can reduce time to appropriate antibiotic administration. Consultation to arrange biliary decompression can be expedited as well.
EVALUATION OF JAUNDICED PATIENTS AND THOSE WITH SUSPECTED BILIARY OBSTRUCTION

In patients with jaundice, focused ultrasound can help differentiate obstructive from nonobstructive causes. Dilation of the CBD and intrahepatic ducts indicates outflow obstruction of the biliary tracts and an obstructive etiology. Identification of biliary obstruction in the setting of acute infection should prompt the physician to consider urgent decompression of the biliary tract.

Discovery of a dilated CBD should prompt the sonographer to follow the CBD as far medially as possible. The most common cause of biliary obstruction is choledocholithiasis, for which transabdominal ultrasound has a specificity of up to 95%. It should be noted, however, that ultrasound is not a specific modality for distinguishing the cause of biliary obstruction with the isolated finding of CBD dilation. Further imaging is often required.

ASCITES EVALUATION AND ULTRASOUND-GUIDED PARACENTESIS

Bedside ultrasound can rapidly identify ascites and visualize the relationship of pockets of ascites to adjacent bowel and other abdominal structures. If paracentesis is required, ultrasound allows the user to choose a location that maximizes the chance for a successful procedure while minimizing the chance of damage to nearby structures.

### NASOGASTRIC TUBES

The Salem Sump tube is the most commonly used nasogastric tube (NGT) in the emergency department (ED). The Salem Sump is a double-lumen tube with multiple distal suction eyes. The second lumen allows venting during suction, which prevents invagination and subsequent gastric injury. Indications for its use include gastric evacuation or decompression, diagnostic aspiration of gastric contents, and infusion of therapeutic agents. Intermittent suction may be set at a pressure of less than 120 mm Hg. A Levin tube is a single-lumen tube with multiple distal openings for suction, referred to as “eyes.” The Levin tube’s relatively large internal diameter makes it ideal for rapid decompression or drug infusion. Intermittent suction may be set at a level lower than 40 mm Hg. A Levin tube has the same uses as the Salem tube except that it may not be used for long-term gastric evacuation.

**INDICATIONS AND CONTRAINDICATIONS**

Box 46.1 lists the indications for and contraindications to the use of NGTs in the ED.

**INSERTION PROCEDURE**

Inserting an NGT may cause the patient to cough, vomit, retch, or sneeze. Because traumatic epistaxis is common, protective apparel should be worn when placing an NGT—gloves, gown, and mask. The patient should be placed in either an upright or Fowler position.

**KEY POINTS**

- Nonfunctional feeding tubes can be safely replaced in the emergency department with a commercial tube or by making a few simple alterations to a standard Foley catheter to prolong its longevity.
- Gastroesophageal balloon tamponade tubes are used only for life-threatening variceal bleeding that is refractory to standard, first-line endoscopic and pharmacologic treatment. There is no absolute contraindication to the use of such tubes as a heroic, lifesaving measure.

**Tips and Tricks**

**Inserting a Nasogastric Tube**

Warming the tube will make it more pliable and easier to advance along the curvature from the nasopharynx into the oropharynx.

Flexing the patient’s neck can help direct the tube from the oropharynx into the esophagus.

If choking, gagging, or muffling of the voice occurs, withdraw the tube to the oropharynx only. Do not remove the tube completely, or it must be repassed through the nasopharynx into the oropharynx, which is usually the most difficult and painful part of the procedure.

The tube can coil within the patient’s mouth; if problems occur when placing or verifying placement of the tube, always check the mouth.

In an unconscious patient, elevating the jaw will move the trachea anteriorly, a maneuver that can relieve pressure on the esophagus and make it easier to pass the tube.

A lubricated, soft nasopharyngeal airway may be inserted if neither naris appears to be amenable to placement of the larger, more rigid nasogastric tube (NGT). The nasopharyngeal airway may be used to dilate the nasal passage for a few minutes and then removed to allow another attempt at placing the NGT. Alternatively, a smaller NGT may be passed through the nasopharyngeal airway into the esophagus.

1. **Estimation of Tube Length**

To place the drainage eyes in the proper location in the stomach (Fig. 46.1), the length of tube to be inserted can be estimated by adding the following three measurements together:

   a: Measurement from the patient’s xiphoid process to the earlobe
   b: Measurement from the earlobe to the tip of the nose
   c: 15 cm

2. **Nares Patency Check, Anesthesia, and Vasoconstriction**

Patency of the nares should be checked before placing an NGT. This can be done by direct visualization or by having
the patient sniff or blow out of each nostril with the other naris occluded. Topical anesthetic spray or ointment should be used to decrease the discomfort and gagging associated with tube placement. The more patent nostril should be used for the procedure.

**PRETREATMENT MEDICATIONS** Placement of an NGT is one of the most painful routine procedures performed in the ED. In nonemergency situations it is best practice to treat the patient with nasal vasoconstrictors and anesthetics before placing the tube.⁴

Vasoconstrictors may be used 3 to 5 minutes before the procedure to decrease traumatic bleeding. Phenylephrine (Neo-Synephrine 0.5%) or oxymetazoline (Afrin 0.05%) is typically used. Vasoconstrictors must be used with caution in hypertensive patients.

Application of lidocaine before inserting an NGT has been shown to significantly decrease pain during the procedure.⁵⁻⁷ Lidocaine can be delivered as viscous, nebulized, or atomized preparations. Application of viscous lidocaine to the nasal passage combined with lidocaine spray applied to the posterior pharynx has been shown to be superior to other forms of anesthetics when placing an NGT or transnasal bronchoscope.⁶,⁸ However, no definitive study or review article has determined the best concentration, form, or dose of lidocaine to use.⁷

**LIDOCAINE OPTIONS**
- Viscous lidocaine—5 to 10 mL of 2% lidocaine applied to an adult nasal passage 0 to 5 minutes before NGT placement combined with lidocaine spray applied to the posterior pharynx.⁵,⁸,⁹ Introduce 3 mL of 2% viscous lidocaine into the nostril and then have the patient snort the medication.

---

**BOX 46.1 Indications for and Contraindications to the Use of Nasogastric Tubes**

**Indications**
- In gastrointestinal bleeding, to monitor blood loss, which may help differentiate upper from lower tract sources of bleeding
- In intubated patients, to decrease risk for pulmonary aspiration, treat gastric distention, and deliver medications
- Decompression of intestinal obstruction
- Treatment of paralytic ileus, intractable vomiting
- Treatment of gastric outlet obstruction and distention
- In trauma patients, to evaluate for transdiaphragmatic hernia when the nasogastric tube is seen above the diaphragm on a chest radiograph
- Rightward deviation of the tube may be seen on a chest radiograph in patients with aortic dissection

**Relative Contraindications**
- Facial fractures: trauma patients with suspected cribiform plate or midfacial fractures are susceptible to intracranial placement of nasogastric tubes
- Severe coagulopathy
- Ingestions likely to cause upper gastrointestinal perforation, such as alkali and highly volatile substances
- Esophageal strictures
- Recent bariatric surgery

---

**Fig. 46.1** To estimate the length of nasogastric tube to be inserted, add together the measurement from the patient’s xiphoid process to the earlobe (A), plus the measurement from the earlobe to the tip of the nose (B), plus 15 cm (C). (From Samuels LE. Nasogastric and feeding tube placement. In: Roberts JR, Hedges JR, editors. Clinical procedures in emergency medicine. 4th ed. Philadelphia: Saunders; 2004. pp. 794-816.)
The tube is passed through the nose into the posterior pharynx with the fingers in the pharynx to direct the tube into proper location (Fig. 46.3).²

Verifying Tube Placement
Radiographic verification is the most sensitive test to detect proper placement, but it is not necessary to meet the standard of care. Methods that are normally used to verify tube placement at the bedside are as follows:

• Insufflation of air causing or resulting in borborygmi (gurgling) sounds heard over the epigastrium verifies that the tube is in the stomach.
• Aspiration of gastric fluid; a pH less than 4 is correlated with a 95% likelihood that the tip of the tube is in the stomach.
• In a conscious patient, normal clear speech without coughing is suggestive of proper tube placement.¹²

Securing the Nasogastric Tube
The NGT is taped in place once proper tube insertion is verified. Silk tape is torn into a butterfly configuration, with one end of the tape placed on the nose and the torn ends of the tape wrapped around the tube in opposite directions. Tincture of benzocaine can be used on the skin before placement of the tape to more securely adhere both the tube and tape.

COMPLICATIONS
Placement of an NGT has a complication rate between 0.5% and 1.5%. Common complications are as follows¹³:

• Epistaxis
• Tracheal or bronchial placement
• Pneumothorax
• Intracranial placement
• Esophageal or pharyngeal perforation
• Gastric or duodenal rupture
• Esophageal obstruction or rupture
Types of gastrostomy tubes.

- Gastrothorax and tension gastrothorax
- Pulmonary aspiration; the NGT may induce a hypersalivation response, a depressed cough reflex, or mechanical or physiologic impairment of the glottis

TRANSABDOMINAL FEEDING TUBES

Feeding tubes are placed to provide long-term nutritional support. They are classified both by the location of their terminal lumen and by the method of placement. Gastrostomy tubes have a terminal lumen located within the stomach and are now typically placed via a percutaneous endoscopic technique; they are thus called PEG (percutaneous, endoscopically placed gastrostomy) tubes (Fig. 46.4). Several manufacturers make various types of PEG tubes. The other most frequently encountered feeding tube is a J tube, or jejunostomy tube. Such tubes are longer, smaller-caliber tubes that terminate in the jejunum. Unlike a gastrostomy tube, a J tube does not have an inflated balloon on its terminal end.

The classic open surgical gastrostomy procedure is less commonly performed than the percutaneous techniques. Percutaneous tubes can be placed by a gastroenterologist via endoscopy or by a radiologist via fluoroscopy. Fewer complications are seen with radiographically placed tubes than with tubes placed either by an open technique or endoscopically (Fig. 46.5).17,18

MAJOR COMPLICATIONS OF TRANSABDOMINAL FEEDING TUBES

Serious complications seen with transabdominal feeding tubes almost always require hospitalization and gastroenterology or surgery consultation (or both). Intestinal complications include obstruction, perforations, gastrointestinal (GI) bleeding, volvulus, and gastric outlet obstruction. Serious infections include bacteremia, pulmonary aspiration, sepsis, peritonitis, advanced local cellulitis, and necrotizing fasciitis.19-22 Other complications of gastrostomy tubes are prolapse with and without intestinal obstruction, extraluminal position of the tube, and fistula formation.23 Patients may also demonstrate minor and major electrolyte abnormalities and, rarely, pneumothorax.

REPLACING A TUBE

Transabdominal feeding tubes must be replaced (Fig. 46.6) for many reasons, including expulsion, malfunction, leakage, tube deterioration resulting in cracks or fissures, and aneurysmal dilations of the tube. It is important that a patient’s tube be correctly identified with respect to type, size, and manufacturer before an attempt at replacement. A dislodged tube should be replaced as quickly as possible to maintain patency of the feeding tube tract. When replacing a feeding tube it is important to clarify whether the terminal end was in the stomach versus the jejunum. After placement, the anchoring balloon in the replacement tube should be inflated in G tubes but never in J tubes.

REMOVING A NONFUNCTIONAL TUBE

If the nonfunctioning PEG tube was placed under fluoroscopic guidance by a radiologist, it can usually be removed by deflation of the balloon and gentle retraction. Some devices have
**FOLEY CATHETERS VERSUS COMMERCIAL FEEDING TUBE PRODUCTS AS REPLACEMENTS**

Both commercially available feeding tubes and Foley catheters can be used to replace a dislodged feeding tube. Commercial feeding tubes are more expensive than Foley catheters. Studies have found that a silicone Foley catheter with a retention disk and ring has the same efficacy and complication rate as a commercially available replacement gastrostomy tube. The retention disk and ring are used to prevent distal migration of the tube into the GI tract.  

However, many institutions do not stock silicone Foley catheters.

**Foley Catheters Used as Replacement Feeding Tubes**

A few simple modifications to a standard Foley catheter can maximize its longevity as a feeding tube, as well as reduce the chance of complications. When using a Foley catheter to replace a feeding tube, an external bolster, or anchor, is fashioned to prevent ingress of the tube into the ostomy and distal migration into the GI tract. An external bolster may be constructed by cutting a 3-cm section from a large rubber catheter. The outer bolster should be secured approximately 1 cm from the skin to prevent trapping of moisture and maceration. Its construction is as follows:

1. Cut a 3-cm section from the proximal segment of a Foley catheter to be used as a bolster, the end without the balloon. A silicone catheter is preferred over a latex one (Fig. 46.7, A).
2. Fold this segment in half and make a diagonal cut on each side of the fold to create a diamond-shaped opening in the middle of each side of the 3-cm segment of tubing. Cut the holes slightly smaller than the tube to be inserted and used as the feeding tube to ensure a snug fit of the bolster on the replacement tube (see Fig. 46.7, B and C).
3. Insert a hemostat through the two holes created in the bolster.
4. Grab the proximal end of the replacement tube with the hemostat and pull the tube through the bolster (see Fig. 46.7, D).
5. Advance the bolster to its proper location about 1 cm above the skin of the abdomen (see Fig. 46.7, E).

**Verifying Tube Location**

No standard method for verifying tube placement has been established. The safest and best practice is to obtain radiographic confirmation when a feeding tube is replaced. Radiographic confirmation should be obtained in the following circumstances:

- With replacement of a recently placed feeding tube (less than 3 months) because the tract may not be mature
- When tube replacement was difficult

---

**Steps for replacing a transabdominal feeding tube.**

- Determine location and size of tube
  - Use same size as previous tube
  - Check old records for size
  - If unknown, start with 16F G tube or Foley for gastric tubes, and smaller 8–14F for J tubes

- Clean skin (betadine)

- Remove old tube—deflate balloon and apply gentle traction or gentle traction alone if flange is known to be present.
  - Do not attempt removal if current tube has a bolster or one is suspected based on method of placement

- Lubricate stoma and tract with water soluble material

- Attempt to pass the replacement tube using gentle pressure

- Successfully placed—inflate tube with 20mL of water if located in stomach. Do not inflate balloons in the jejunum.
  - Use smaller caliber tube and re-attempt.

- Obtain radiographs with water-soluble contrast material to ensure proper location and functioning (see text)

- Not successful—consult surgery, gastroenterology, or interventional radiology

- Unsuccessfully placed—deflate balloon and re-attempt.

---

Fig. 46.6 Steps for replacing a transabdominal feeding tube.

---

a flange rather than a balloon, and these flanges usually collapse with slow, gentle traction. If the tube was placed by a gastroenterologist or a surgeon, it may have an anchoring device or an internal component that prevents the tube from becoming dislodged from the gastrostomy tract. Such a tube cannot be removed by gentle traction alone; the internal component must be removed endoscopically. If resistance is met when attempting removal, a gastroenterologist, interventional radiologist, or surgeon should be consulted.

As an alternative method, the tube is lifted off the abdominal wall skin to allow the tube to be cut as close to the skin as possible. The internal component is then pushed into the GI tract so that it is free to pass through the intestines and be eliminated rectally. Most internal components pass within 2 weeks. There have, however, been reported cases of intestinal obstruction, perforation, and rarely death with this method.  

The internal component is less likely to pass without complications in children than in adults. If this technique is used, reliable patient follow-up is needed for serial abdominal radiographs. Radiographs should be taken within 1 week to monitor the progress of the component through the GI tract. If the internal component has not passed within 1 to 2 weeks, impaction has probably occurred, and endoscopic removal should be considered. Primary endoscopic removal is also advised in patients with intestinal obstruction, pseudoobstruction, pyloric stenosis, intestinal stricture, history of irradiation, and inflammatory bowel disease.
When gastric material cannot be aspirated after placement
When the patient is unable to communicate about symptoms such as pain with tube placement and use

Radiographic confirmation can be accomplished with fluoroscopy or by injection of water-soluble contrast material into the tube followed by plain radiography. Typically, 20 to 30 mL of contrast material is injected into the tube via a catheter tip syringe. An abdominal film should be obtained within 1 to 2 minutes. Generally, a flat-plate abdominal view is sufficient to verify tube placement. If insertion of the tube was very difficult or malposition is suspected, a two-view abdominal film may be required to ensure proper tube location. Proper location of the replaced tube is indicated by (1) ease of injection of the contrast material and (2) visualization of the gastric and intestinal walls as they are outlined by the contrast material. If extravasation of the dye is seen outside the stomach or intestine, tube malposition is verified.

Recently, two newer verification techniques have been described in small studies. The first uses air insufflation through the replacement tube to verify proper placement. Once the tube is replaced, a total of 240 mL of air is insufflated through the tube with a 60-mL syringe. The tube is considered properly replaced if it can be seen clearly within an air-distended stomach on a plain radiograph. The second technique was described in a small study with 10 subjects. Ultrasound was used to visualize the new tube as it was placed in the established tract. After insertion, color Doppler was applied over the catheter tip while it was gently oscillated to enhance visualization

**CLOGGED FEEDING TUBES**

Larger-diameter feeding tubes are less likely than smaller tubes to become clogged. A tube can become obstructed if kinking occurs or the lumen is clogged with debris. A recently
placed or reinserted tube is prone to kinking. A kink can be treated by withdrawing the tube a few centimeters and then advancing it again. Contrast-enhanced radiographs should be obtained whenever significant tube manipulation has occurred to evaluate for patency and proper location. A persistently clogged tube needs to be removed and replaced.

If a feeding tube is clogged by debris, the following approaches can be used to unclog the tube:

- Milk the external part of the tube backward in an attempt to expel the debris.
- Irrigate with small aliquots of carbonated beverages.
- Irrigate with small aliquots of warm water at high pressure; use a small syringe (5 to 10 mL) with manual injection.

Instrumentation of the tube with either a Fogarty arterial embolectomy catheter or a nasal foreign body catheter can also be attempted. The length of the feeding tube external to the abdomen should be measured and the Fogarty catheter inserted only to this length. An instrument should never be inserted past the abdominal wall skin. The balloon on the catheter can be inflated in the tube if an obstruction is encountered and then further advanced to probe the entire length of the external tube. The catheter should not be withdrawn with the balloon inflated because this action might cause removal of the feeding tube. In a 10 French (10F) or 12F tube, a No. 4 embolectomy catheter should be used; a 14F tube requires a No. 5 embolectomy catheter.

If a feeding tube has been unclogged by force or instrumentation, water-soluble contrast–enhanced radiographs should be obtained to verify proper tube placement, as well as to evaluate for tube perforation.

**GASTROESOPHAGEAL BALLOON TAMponade**

Variceal bleeding is a leading cause of significant morbidity and mortality in patients with cirrhosis. Sengstaken and Blakemore first described the use of a double-balloon tamponade system to control variceal bleeding in 1950. Sengstaken-Blakemore (SB) tubes are not advocated as primary or secondary therapy for cirrhotic patients; they are used as rescue therapy for life-threatening variceal bleeding.

Two gastroesophageal balloon tubes are in general use. The SB tubes have three lumens—a gastric balloon, an esophageal balloon, and a gastric aspiration port. The Minnesota tube has a fourth lumen for esophageal aspiration.

The indication for gastroesophageal balloon tamponade (GEBT) is severe, acute variceal bleeding that is refractory to available first-line interventions such as sclerotherapy and vasoconstrictor therapy. Relative contraindications are esophageal strictures, recent esophageal surgery, and decreased level of consciousness without airway protection. A patient with a decreased level of consciousness should always be intubated before insertion of an SB tube.

**PROCEDURE**

The following equipment is needed:

- Gloves and personal protective equipment
- GEBT tube
- NGT if the tamponade tube does not have an esophageal aspiration lumen
- Traction device
- Manometer or sphygmomanometer
- Y-tube connector
- Emesis basin
- Water-soluble lubricant
- Suction device with connectors
- Tubing to connect to suction
- Clamps or nonserrated hemostats
- Silk sutures
- Tape and gauze

The procedure is as follows:

1. If needed, intubate the patient before placement of the tube.
2. Check the balloons for patency and leaks before use: use 100-mL increments of air to inflate the gastric balloon, and check the pressure with a sphygmomanometer after each increment. These pressure measurements should be recorded for each 100-mL increment of air and will be used to compare pressure readings once the tube has been inserted (step 12). The pressure in the gastric balloon should not increase more than 15 mm Hg with insufflation of each 100 mL of air.
3. If an NGT is to be inserted, tie a suture around it and the GEBT tube to secure them together. The tip of the NGT should be located 3 to 4 cm proximal to the esophageal balloon.
4. Lubricate the tube or tubes with a water-soluble lubricant.
5. Position the patient either upright angled at 45 degrees or in the left lateral decubitus position.
6. Anesthetize the posterior pharynx or nasopharynx with topical anesthetic spray or nebulized lidocaine (or both; see previous discussion on NGT insertion).
7. Place an NGT and evacuate the stomach before placing a GEBT tube to decrease the chance of emesis and aspiration. Once the gastric contents have been evacuated, remove the NGT.
8. Deflate all balloons and either clamp the ends of the tubes or place plugs in each lumen if provided by the manufacturer.
9. Pass the tube to a minimum level of 50 cm as marked on the tube.
10. Connect suction to the gastric and esophageal lumens to check for contents and to decrease the likelihood of aspiration.
11. Confirm proper tube placement with radiographs even if gastric contents or blood is evacuated. The tip of the tube or balloon should be located below the diaphragm if properly placed.
12. Remove the clamps or plugs and inflate the gastric balloon slowly with 100-mL increments of air. Check the pressure of the gastric balloon after each injection; with each 100 mL of air insufflated, the pressure should not be more than 15 mm Hg higher than the pressure measurements previously obtained for the same volume of air (step 2). If the pressure rises by more than 15 mm Hg, the balloon may be located in the esophagus and not in the stomach. If this occurs, deflate the balloon and obtain additional radiographs.

**SECTION IV GASTROINTESTINAL DISEASES**
another radiograph to ensure proper tube location before resuming air insufflation. Generally, 400 to 500 mL of air must be insufflated to obtain the proper pressure; check the manufacturer’s recommendation for the tube being used.

13. Once proper pressure is obtained, clamp or plug the lumens of the gastric balloon and the air inlet.

14. Gently pull back on the GEBT tube until it snugs up against the diaphragm and applies pressure at the gastroesophageal junction.

15. Secure the GEBT tube to the traction device to be used while applying a small amount of tension to the GEBT tube to keep constant pressure on the lower esophageal sphincter. The traction devices may be an orthopedic trapeze apparatus or another device provided by the manufacturer.

16. If the tube was passed nasally, place the sponge rubber cuffs provided by the manufacturer into each nostril or pad the nostrils with gauze to prevent pressure ulcers.

17. Once the tube is properly placed and secured, lavage the stomach with room-temperature water to assess for active bleeding. Attach the gastric lumen to high-pressure, intermittent suction.

18. If blood continues to be aspirated from the gastric lumen, the esophageal balloon can be inflated to a minimum pressure level to control the bleeding or to the maximum pressure advised by the manufacturer (typically 30 to 45 mm Hg). Clamp or plug the lumen of the esophageal balloon once a desired pressure level is obtained.

19. Frequent manometer readings of the esophageal balloon should be obtained to decrease the risk for complications.

20. If bleeding continues, the most likely source is gastric; tension on the gastric balloon may be increased gradually to help control the bleeding.

21. Obtain radiographs any time that the position of the tube comes into question.

22. Once the bleeding is controlled, attempts should be made to decrease the pressure in the esophageal balloon by increments of 5 mm Hg every 3 hours until a pressure of 25 mm Hg is reached (or as recommended by the manufacturer). Typically, a pressure of 25 mm Hg can be maintained for 12 to 24 hours if the bleeding is controlled.

23. If the esophageal balloon requires inflation at pressures greater than 30 mm Hg, the balloon should be deflated every 6 hours for 5-minute intervals to prevent complications such as mucosal ischemia and necrosis.

24. To prevent vomiting and aspiration, the esophagus must be emptied continuously even if the esophageal balloon is not inflated. The gastric balloon will preclude passage of secretions into the stomach. Aspirate with either an esophageal aspiration port in a Minnesota tube or an NGT with its tip located in the esophagus next to the GEBT tube. The volume of oral and esophageal secretions can total up to 1500 mL/day.

25. Once the GEBT tube is properly inserted and bleeding has been controlled, the tube should not be disturbed for 12 to 24 hours.

26. If bleeding cannot be controlled, further therapies are indicated, such as emergency surgery, endoscopic interventions, or angiographic embolization.

COMPPLICATIONS

Use of the GEBT tube is associated with many minor and major complications (Box 46.2). Such tubes should be used only when life-threatening bleeding occurs and other available modalities have failed. Approximately 8% to 16% of patients treated with GEBT tubes have a major complication, with reported mortality rates of 3%.34-36

Complications of Bariatric Surgery

Robert F. Poirier

KEY POINTS

- Laparoscopic Roux-en-Y gastric bypass is the most commonly performed bariatric procedure in the United States.
- Pulmonary embolism (30% to 40%) is the most common cause of death after bariatric surgery, followed by cardiac events (25%) and anastomotic leaks (20%). Dumping syndrome, wound infections, strictures, and stomal ulcerations are common complications.
- Acute gastric distention is a rare but potentially deadly early postoperative complication that requires decompression.
- A nasogastric tube could perforate the pouch site in patients who have recently undergone surgery.
- Abdominal pain without vomiting in the early postoperative weeks might represent a small bowel obstruction or internal hernia.
- Laparoscopic adjustable gastric banding (LAGB) is the most commonly performed bariatric procedure in Europe and is becoming more common in the United States.
- Acute anterior or posterior gastric band slippage is the most common complication of LAGB requiring emergency treatment (band deflation).
- LAGB has the lowest morbidity and mortality of all currently performed bariatric procedures.

EPIDEMIOLOGY

The prevalence of morbid obesity has risen more than fourfold since 1986. Currently, 1.7 billion people worldwide are considered obese and approximately 60% of the U.S. population is overweight. In excess of 100 billion dollars is spent annually on obesity health-care–related costs.

To be considered morbidly obese, one must have either a body mass index (BMI) greater than 40 kg/m² or a BMI of 35 to 40 kg/m² with comorbid conditions. More than 15 million Americans currently have BMI levels that make them eligible for bariatric surgery. In the United States only about 1% of eligible patients undergo bariatric surgery.

Morbid obesity promotes the development of diabetes mellitus, hypertension, dyslipidemia, cardiovascular disease, gastroesophageal reflux, asthma, and obstructive sleep apnea. Premature death from obesity now rivals the mortality rates related to smoking, with more than 300,000 deaths attributable to obesity per year. Bariatric surgery is the most effective and durable treatment to achieve weight loss and its associated comorbidity. Five-year mortality is reduced 89% in severely obese patients who undergo weight loss surgery. Fifteen-year survival increases by one third in patients who undergo bariatric surgery in comparison with those who do not. New laparoscopic surgical techniques have contributed to the growing demand for and acceptance of bariatric surgery. Approximately 4925 bariatric procedures were performed in 1990, as compared with an estimated 220,000 in 2008. Bariatric surgery is now the second most common abdominal operation in the United States.

Women are more likely than men to choose bariatric surgery. It is estimated that men make up 36% of the morbidly obese population in the United States, although they account for less than 20% of patients choosing weight loss surgery each year. The typical demographic profile of a bariatric surgery patient is a woman 35 to 49 years of age with private insurance who belongs to a higher socioeconomic class.

Recent trends suggest that higher-risk, older patients are undergoing bariatric procedures with greater frequency; surprisingly, they demonstrate postoperative morbidity and mortality rates similar to those in the general population. Rates of perioperative complications, reoperation, hospital readmission, and emergency department (ED) visits have been falling. The rates for these indicators are highest with gastric bypass followed by sleeve gastrectomy and lowest for laparoscopic adjustable gastric banding (LAGB). Overall, in-hospital mortality rates are between 0.05% and 0.2%, and 30-day mortality rates have been reported to range between 0.05% and 2%.

Complications of bariatric surgery are common and are generally initially treated in the ED. Up to 20% of patients are admitted for a postoperative complication within 1 year of the bariatric procedure; this rate increases to 40% within 3 years. The potential postoperative complications of the various bariatric procedures have predictable timing and clinical manifestations.

TYPES OF BARIATRIC SURGERY: ROUX-EN-Y AND GASTRIC BANDING

The two most common types of bariatric surgery in the United States are the Roux-en-Y gastric bypass (RYGBP) (54%) and adjustable gastric banding (39%). Adjustable gastric banding
continues to rapidly gain in popularity since initial federal approval in 2001.\(^7\)

Caloric restriction and malabsorption are the principal means of weight loss. In the United States, weight loss procedures that combine both restrictive and malabsorptive components are the most popular. RYGBP, biliopancreatic diversion (BPD), and BPD with duodenal switch are examples of techniques that involve both malabsorption and restriction. In Europe, the preference is for purely restrictive bariatric procedures.

**MALABSORPTION**

Surgical techniques that induce malabsorption were the first attempted. Malabsorptive techniques were thought to be the most effective method of achieving rapid and sustained weight loss. Surgeons initially connected the proximal jejunum to a distal portion of the ileum or ascending colon in a procedure known as jejunooileal bypass (Fig. 47.1). This technique resulted in severe diarrhea, dangerous metabolic derangements, arthropathy, renal calculi, gallstones, liver disease, and short bowel syndrome. Gastric bypass has been shown to be a more effective malabsorptive procedure with fewer side effects than those associated with jejunoileal bypass. Malabsorptive procedures still in current use include laparoscopic RYGBP, BPD, duodenal switch, and isolated intestinal bypass.

**RESTRICTION**

Purely restrictive procedures are less effective than malabsorptive techniques.\(^6\) Restrictive surgeries act by reducing oral intake through induction of early satiety. However, some areas of the stomach easily dilate over time, which causes gradual increases in perceived hunger and subsequent food intake. Restrictive procedures are more successful when the lesser-curve gastric pouch is 15 mL or smaller.\(^4\) Restrictive weight loss procedures such as vertical banded gastroplasty and isolated partial gastrectomy (sleeve gastrectomy) have fallen out of favor. LAGB is the most common, poses the least risk, and is the most effective restrictive technique currently performed.\(^10\)

**ROUX-EN-Y GASTRIC BYPASS**

The RYGBP procedure creates a gastric pouch from the proximal portion of the lesser curvature of the stomach that can hold about 15 to 30 mL of fluid and food (Fig. 47.2). A portion of the distal end of the small bowel is connected to this pouch to create a concurrent malabsorptive process. Historically, RYGBP was an open procedure, but currently the majority are performed laparoscopically.

Early postoperative complications of RYGBP include obstruction of the bypassed small bowel segment, obstruction of the Roux limb, anastomotic leak, and gastrointestinal (GI) or intraperitoneal bleeding. Pulmonary embolism, a rare postoperative complication, remains the most common cause of postoperative death, followed by complications resulting from anastomotic leaks. Other complications include pneumonia, myocardial infarction, renal failure secondary to rhabdomyolysis, and nutritional deficiencies.
Late complications generally involve both anatomic and systemic complications. Anatomic complications include esophageal reflux, chronic abdominal pain, internal hernias, ulcers, stricture, stenosis, and bowel obstruction. Systemic complications are manifested mostly as nutritional deficiencies. Clinical manifestations include anemia (iron deficiency), osteopenic fractures (calcium deficiency), fatigue and lower extremity edema (protein-calorie malnutrition), chronic pain and proximal muscle weakness (vitamin D deficiency), visual deficits (vitamin A deficiency), and vague neurologic symptoms (thiamine, folate, and vitamin B₁₂ deficiencies).

Complications of Open versus Laparoscopic Procedures

Wound infections and incisional hernias are more common with open bariatric procedures (7% and 9%, respectively) than with laparoscopic procedures (3% and 0.5%, respectively). Patients who have undergone laparoscopic gastric bypass have a slightly higher rate of small bowel obstruction, anastomotic stenosis, internal hernias, and GI hemorrhage. Pulmonary embolism, pneumonia, and anastomotic leaks have similar incidences after both open and laparoscopic procedures. Stomal stenosis manifested as postprandial epigastric pain and vomiting of undigested food is thought to be more common after laparoscopic RYGBP because a mechanical stapler is used instead of the hand-sewn methods with open RYGBP. Endoscopy often both diagnoses and treats this complication.

Specific Clinical Presentations

Persistent, severe vomiting can be caused by anastomotic strictures. Strictures can usually be treated by endoscopic balloon dilation but occasionally require surgical revision. Some episodes of nausea and vomiting are common during the immediate postoperative period, but if the vomiting persists, an anastomotic stricture may have formed.

Obstruction of the Roux limb requires percutaneous decompression. Patients with such an obstruction experience nausea, vomiting, abdominal pain, and distention. Diagnosis may require computed tomography (CT).

The occurrence of acute fever and tachycardia within weeks of a Roux-en-Y procedure suggests an anastomotic leak with or without abscess formation. The symptoms are often subtle but can include dyspnea, unexplained sepsis, changes in mental status, and restlessness. Peritoneal signs are often lacking. Because abdominal examination of morbidly obese patients is unreliable, the diagnosis is best accomplished through imaging studies. CT of the abdomen and pelvis with oral and intravenous (IV) administration of a contrast agent is the modality of choice. If the patient is unable to undergo CT because of the weight limitations of the CT table, an upper GI radiographic series should be obtained. The false-negative rate is high (up to 44%) with CT and other imaging studies for the evaluation of anastomotic leaks. Laparoscopy should be considered in cases of negative imaging but high pretest probability of an anastomotic leak. Esophageal reflux occurs infrequently after this procedure but may represent damage to the lower esophageal sphincter or impaired gastric emptying secondary to a distal obstruction. Overfilling of the pouch, operative vagal nerve injury, or stomal stricture can lead to gastroesophageal reflux disease (GERD). Educating patients to avoid overeating, chew food properly, use acid suppression medication, and eat small frequent meals reduces the incidence of GERD.

Diarrhea with malodorous flatulence may result from a short Roux limb and usually resolves spontaneously. Persistent diarrhea after weight stabilization, however, should raise suspicion of bacterial overgrowth in the bypassed tract.

Dumping syndrome consisting of abdominal cramping, nausea, vomiting, and diarrhea can be seen immediately postoperatively and may last up to 12 to 18 months. Noncompliance with diet is the most common and preventable cause. Treatment includes rehydration, electrolyte correction, and education of the patient regarding diet.

Constipation may result from decreased fiber intake.

Cholelithiasis may develop during the period of initial rapid weight loss. Biliary colic and cholecystitis are high on the differential diagnosis list for abdominal pain in patients with ongoing reductions in weight. Prophylactic cholecystectomy was often performed during open RYGBP. The transition to laparoscopic surgery for most RYGBP procedures has led to a decrease in prophylactic cholecystectomy and thus an increase in cholelithiasis rates.

Bleeding may occur at any anastomotic site but is most common and dangerous in the gastrojejunalostomy area. It often results in melena, hematemesis, hematochezia, or hypotension (or any combination of these findings) secondary to upper GI bleeding. Upper endoscopy is the most reliable way to confirm blood loss from this site. Bleeding at other anastomotic sites (jejunojejunostomy and the transected gastric remnant) is usually self-limited and managed nonoperatively. Stomal ulcers can occur 2 to 4 months after surgery and are identified by endoscopy. Many can be treated on an outpatient basis with proton pump inhibitors or sucralfate.

LAPAROSCOPIC ADJUSTABLE GASTRIC BANDING

The LAP-BAND (Allergan, Inc., Irvine, CA) is an adjustable device that is laparoscopically secured around the upper portion of the stomach (Fig. 47.3). The band is connected by a tube to a port implanted under the skin. Surgeons may adjust the extent of constriction (restriction) of the LAP-BAND by injecting saline into the subcutaneous port. Increased restriction limits food intake; adjustments can be made in response to adverse symptoms or patient preference, thereby allowing some control over the weight loss process. Operative risks for LAGB are less than those for RYGBP.

In 2007 the Food and Drug Administration (FDA) approved a second gastric banding device called the Realize Adjustable Gastric Band. The Heliogast and Midband adjustable gastric bands are available only outside the United States and have not been approved by the FDA. All gastric banding devices work similarly. In 2011 the U.S. FDA approved expanding the use of gastric banding surgery for an additional 27 million American patients with mild obesity (BMI of 30 to 35 kg/m²) who have one obesity-related health condition (e.g., hypertension, diabetes mellitus).

Complications

LAGB is generally performed as outpatient surgery. Immediate postoperative vomiting is usually caused by gastric wall edema under the band. Inflation of the band during surgery increases the likelihood of gastric wall edema. IV hydration is required until the edema subsides. Maintenance of nothing
CHAPTER 47  COMPlications of Bariatric Surgery

A GI swallow study and surgical consultation should be obtained after any band deflation. Symptoms should resolve over a couple of days after deflation. Surgery is often required to definitively repair gastric band slippage.

Gastric stoma obstruction by food, swelling, or hematoma can be an early or late complication. Partial obstruction can be treated conservatively with hydration and NPO status. Complete obstruction often requires band deflation and surgery to reposition the band.

Band erosion can occur in up to 4% of patients over time. The band can erode and migrate silently into the stomach. Peritonitis is often absent, but GI bleeding and bowel obstruction can occur. Port site infections may be the first sign of band erosion, and endoscopy is the best method to diagnose band erosion. Upper GI studies and CT scans can assist in making the diagnosis as well. Removal of the band and repair of the stomach are required.

Gastric injury as a result of stomach perforation occurs rarely. One to 2 days following band placement an acute abdomen may develop. IV fluids, broad-spectrum antibiotics, NPO status, and surgical consultation with subsequent repair of the stomach are required.

Gastric necrosis of the stomach wall is a late complication that often results from ischemia caused by a combination of gastric prolapse—the part of the stomach below the band herniates up through the device (Fig. 47.4) and pressure from the band. Patients appear ill, with an acute abdomen. Upper GI studies or CT scans show an overly distended gastric pouch. Patients require emergency surgery to remove the band and repair the stomach wall.

By mouth (NPO) and IV steroids are thought to increase the resolution rate.

Immediate postoperative vomiting or dysphagia may also be due to gastroesophageal obstruction caused by proximal band slippage (1% to 3%). Gastric dilation and food intolerance may develop. Gastric necrosis and perforation may result from band migration at any time. A GI swallow study using fluoroscopy is the preferred method of diagnosing band migration, but a two-view upper GI contrast study or abdominal radiograph may capture the position of the radiolucent band. An abdominal CT scan may also demonstrate movement of the band. Band slippage is the most common LAGB complication occurring early to late in the postoperative period. Band slippage rates are decreasing, however, with new placement techniques.

Any patient with signs of obstruction after LAGB should undergo immediate deflation of the band. Emergency physicians can deflate an adjustable gastric band by accessing the subcutaneous anterior abdominal port (see Fig. 47.3). A non-coring Huber needle should be used to remove the amount of saline injected during the previous two adjustments. The patient should know this volume of saline, but if not, one can aspirate all the saline in the reservoir. Fluoroscopy or ultrasound may be required if the port cannot be accessed easily. A GI swallow study and surgical consultation should be obtained after any band deflation. Symptoms should resolve over a couple of days after deflation. Surgery is often required to definitively repair gastric band slippage.

Esophageal and gastric pouch dilation occurs when the band is too tight or patients are not compliant with their diet. The symptoms are similar to those seen with gastric slippage. Upper GI contrast studies make the diagnosis. Treatment is
biliopancreatic diversion–duodenal switch (BPD-DS) procedure. It is considered an improvement on BPD alone because the length of the small intestine is increased to 100 cm, which allows better absorption of nutrients.

A linear (sleeve) gastrectomy in which a restrictive pouch of the lesser curvature is left is also performed during the duodenal switch. BPD-DS with sleeve gastrectomy allows gastric emptying to be somewhat regulated through preservation of a functioning pylorus. The risk for dumping syndrome is subsequently reduced.

Some surgeons prefer to perform only a sleeve gastrectomy in high-risk patients (Fig. 47.7). This simple restrictive procedure avoids intestinal bypass and anastomoses of the GI tract. Side effects such as nutritional deficiencies are rare because only mild malabsorption results from sleeve gastrectomy alone.

**BILIOPANCREATIC DIVERSION**

BPD is popular in Italy (Fig. 47.5). The procedure involves a distal gastrectomy that leaves a 250-mL stomach capacity with a drastic intestinal bypass. Half of the jejunum and ileum are disconnected and reconnected near the terminal ileum. This procedure is particularly effective for severely obese patients (BMI > 50 kg/m²), in whom it causes significant weight loss and reduced morbidity. Less bacterial overgrowth occurs in the bypassed intestine because it is continuously exposed to bile and pancreatic enzymes. Serious complications can result, however, particularly the metabolic abnormalities and nutritional deficiencies seen after aggressive malabsorptive procedures. Hepatic dysfunction can develop in 2% of patients undergoing BPD.

**DUODENAL SWITCH AND SLEEVE GASTRECTOMY**

The duodenal switch procedure is similar to BPD, but the jejunum is connected to the proximal duodenum rather than the ileum (Fig. 47.6). This operation is also known as the

COMPLICATIONS OF BARIATRIC SURGERY

GENERAL COMPLICATIONS
Serious complication rates are lower in hospitals with a high volume of bariatric surgery procedures.16

Pulmonary Embolism
Pulmonary embolism is the leading cause of death after bariatric surgery. Although the postoperative incidence of deep vein thrombosis (DVT) and pulmonary embolism is only 2%, almost one third of affected patients die. The incidence of DVT and pulmonary embolism has not diminished despite the use of pneumatic compression stockings, low-molecular-weight heparin, and various other prophylactic measures. Early postoperative ambulation may be the most important preventive measure in the bariatric population. Lower extremity duplex Doppler ultrasonography for DVT and helical pulmonary CT scanning for pulmonary embolism are the preferred diagnostic studies. If weight limitations prevent performance of a CT scan, ventilation-perfusion scintigraphy should be considered.

Wound Infections, Seromas, and Dehiscence
Wound infections occur in 10% to 15% of patients undergoing open procedures and in 3% to 4% of those treated by laparoscopic techniques. Seromas commonly occur in up to 40% of patients. Although the wound infections may appear superficial, deep extensions may be present in the morbidly obese. Patients with wound infections and fever should undergo contrast-enhanced CT of the abdomen to exclude deep infections.

Intraperitoneal Fluid Collections and Peritonitis
Intraperitoneal fluid collections, abscesses, and peritonitis occur in less than 2% of patients undergoing bariatric procedures. Anastomotic leaks are the most common cause of fluid collections in the early postoperative period. Clinical signs are often subtle, and the diagnosis cannot be made by physical examination alone. Patients may have low-grade fevers, tachycardia, and mild tachypnea. Early surgical consultation should be obtained to facilitate the most efficient evaluation and treatment because life-threatening sepsis may ensue. The poor cardiopulmonary reserve of morbidly obese patients may allow rapid clinical deterioration. Some institutions advocate CT-guided aspiration during initial imaging.

Incisional Hernia
Incisional hernias occur in up to 9% of patients after open RYGBP. Rarely are incisional hernias seen in those who undergo laparoscopic procedures. Physical examination alone confirms the diagnosis.

Gallstones
The incidence of cholelithiasis is 1% to 3% after bariatric surgery. Rapid weight loss is known to promote the formation of gallstones, and most surgeons perform prophylactic cholecystectomy in patients with known cholelithiasis. The distorted anatomy after gastric bypass often precludes successful endoscopic retrograde cholangiopancreatography. Symptomatic biliary disease in patients who have undergone a Roux-en-Y procedure usually requires surgical intervention or percutaneous drainage.

PROCEDURE-SPECIFIC COMPLICATIONS
Box 47.1 lists the most common GI complications of bariatric surgery.12

Anastomotic (Staple Line) Leak
Anastomotic leaks most often occur in the immediate postoperative period, although some leaks are not apparent until weeks after surgery. GI leaks are one of the most serious and potentially deadly complications of gastric bypass surgery. The incidence is up to 6% in patients after first procedures, but it rises 5-fold to 10-fold in patients who undergo revision of the initial procedure.Leaks are difficult to diagnose because of initial nonspecific signs and symptoms: low-grade fever, abdominal tenderness, tachycardia, and respiratory insufficiency, tachycardia, left shoulder pain, anxiety, and a feeling of impending doom. An upper GI radiographic series or abdominal CT scan sometimes confirms the diagnosis by demonstrating extravasation of the oral contrast agent (Gastrografin). However, an upper GI series or CT scan often misses the leak. Many bariatric surgeons question the need for confirmatory studies and believe that patients should be taken to the operating room for laparoscopic examination when tachycardia greater than 120 beats/min and symptoms indicative of a leak are present.17 The most common site of the leak is the gastrojejunostomy anastomosis. Interventional or surgical management is required. Early antibiotic therapy is recommended.

Acute Gastric Distention
Acute gastric distention is a rare, potentially deadly, early postoperative complication. Patients may have pain, nausea, vomiting, abdominal distention, bloating, hiccups, tachycardia, shortness of breath, or referred left shoulder pain. Abdominal plain films or abdominal CT scans usually demonstrate a large air-fluid level in a dilated stomach. Obstruction or edema at the enterostomy site is often the cause of this complication and is best evaluated by CT. Treatment includes percutaneous fine-needle decompression, drainage

via a gastrectomy tube, or surgery for cases of recurrence or rupture. A nasogastric tube should not be used because of possible perforation.

**TIPS AND TRICKS**

Consult the bariatric surgeon or gastroenterologist (if endoscopy is required) early for patients who have previously undergone bariatric surgery.

Do not place a nasogastric tube in patients who have undergone gastric bypass without consultation from the bariatric surgeon. Blind placement of such a tube may result in perforation of the pouch site, particularly in the immediate postoperative period.

Laparoscopy is often required for definitive diagnosis of internal hernias and anastomotic leaks.

Small gastric pouches limit the amount of oral contrast agent that patients can ingest for a computed tomography scan. If contrast is required, patients should be told to sip as much contrast agent as they feel comfortable taking over a 3-hour period before imaging. The scan is then performed, regardless of the amount of contrast ingested.12

**Stomal Stenosis and Anastomotic Strictures**

The incidence of anastomotic strictures occurring at the gastrojejunostomy site varies from 2% to 11%. Patients often have progressive postprandial, epigastric pain and vomiting. Patients are initially unable to tolerate solid foods, with characteristic progression to poor tolerance of liquids over time. Findings on plain radiography and CT of the abdomen are usually unremarkable. Upper endoscopy both diagnoses and treats this condition. Repeated endoscopic balloon dilation of the stricture is often required. Fluoroscopically guided balloon dilation is an alternative treatment.

**Stomal Ulceration**

Stomal ulceration causes severe dyspepsia, burning retrosternal pain, and vomiting. Abdominal plain films, CT scans, and other upper GI radiographic studies are not useful in diagnosing this complication. Endoscopy is the diagnostic modality of choice. Proton pump inhibitors treat stomal ulceration, and antibiotics are prescribed if the patient is found to have coinfection with *Helicobacter pylori.*

**Small Bowel Obstruction and Internal Hernia**

Abdominal pain without vomiting in the early postoperative weeks might represent small bowel obstruction or an internal hernia. Small bowel obstructions and internal hernias are difficult to distinguish and have a combined incidence of 5% within the first postoperative month. Small bowel obstructions are more common after open bariatric surgery because of adhesion formation; internal hernias are more common after laparoscopic surgery. The Roux limb or pancreaticobiliary limb may herniate through the potential spaces created during surgery. Patients have nonspecific symptoms, including abdominal cramping, periumbilical pain, and nausea. Vomiting is uncommon because only minimal secretions are present in the small gastric pouch. Abdominal plain films are nondiagnostic because dilated loops of bowel are not commonly seen. Upper GI studies and abdominal CT are often unable to distinguish between obstruction and hernia. Surgeons may perform laparoscopy early to prevent potential bowel strangulation.

**Dumping Syndrome**

Dumping syndrome occurs in almost half of patients undergoing gastric bypass. Typical symptoms are bloating, abdominal cramping, nausea, diaphoresis, and lightheadedness; the symptoms are more pronounced after eating food with high concentrations of refined sugar. The effects are self-limited and diminish as patients become more selective with their diet.

**DISPOSITION**

Patients who go to the ED because of systemic or GI symptoms after bariatric surgery often have a postoperative complication that mandates hospital admission. They generally need CT, an upper GI radiographic series, endoscopy, or any combination of these imaging modalities. Discharge should be considered only for patients who have been evaluated in consultation with a surgeon or gastroenterologist (or both), who have stable vital signs and minimal pain, and who can easily tolerate oral fluids.

REFERENCES

Asthma affects approximately 4% to 5% of the population in the United States. Although it is the most common chronic disease of childhood, with a prevalence of 5% to 10%, it also affects 7% to 10% of the elderly. Epidemiologic studies suggest that asthma is underdiagnosed and undertreated in all age groups. Part of the problem is that the transient nature of asthma allows many patients to tolerate intermittent respiratory symptoms before seeking medical care. Another important factor resulting in underdiagnosis of asthma is the sometimes nonspecific nature of the symptoms.

About half of cases of asthma develop before 10 years of age and another third before 40 years. The 2:1 male-to-female preponderance of asthma in childhood equals by 30 years of age. The average asthmatic patient has 15 days of restricted activity each year and spends 5.8 days in bed. Approximately 2 million emergency department (ED) visits, 484,000 hospitalizations, and more than 4000 deaths per year are attributed to asthma. In the United States alone, the estimated direct and indirect cost of asthma in all age groups was $56 billion in 2007.

All asthmatic patients have hyperresponsive airways that narrow when exposed to various stimuli: allergic, infectious, pharmacologic, environmental, occupational, exercise related, and emotional.

Allergic asthma occurs when inhaled allergens bind to immunoglobulin E molecules bound to mast cells in the lining of the tracheobronchial tree. During the early response, various mediators are released and cause greater vascular permeability, mucosal edema, and contraction of bronchial smooth muscle. A second wave of reaction, the late response, is seen hours to days later; it involves accumulation of inflammatory cells in the bronchial mucosa, thus perpetuating the reaction. The release of mediators and regulation of the inflammatory process in asthma are complex, redundant, and self-perpetuating.

Although several theories attempt to explain the pathophysiologic changes that occur in nonallergic asthma, none adequately explain all clinically observed phenomena. Research suggests that even patients without atopy have pathophysiology similar to that in atopic patients. Respiratory infections, particularly viral infections, may precipitate bronchospasm. Viruses cause mucosal inflammation and lower the firing threshold of the subendothelial vagal receptors, which results in enhanced airway reactivity that may last up to 8 weeks, even in nonasthmatic persons. Pharmacologic agents, such as aspirin and nonsteroidal antiinflammatory agents, may increase the risk of asthma exacerbations.
compounds, coloring agents, and beta-blockers, also induce acute asthma. In addition, sulfating agents, which are used widely as food preservatives and antioxidants in pharmaceutical products, can exacerbate asthma.

A large variety of occupational dust and fumes may provoke acute airway obstruction. Patients with occupational asthma classically report a cyclic history; they are symptom free during weekends, vacations, and on arrival at work. Exercise may also stimulate an asthma attack. Exercise-induced bronchospasm is usually noted within 5 to 20 minutes after the completion of exercise and is related to thermal changes in the respiratory tree. Exercising in a cold, dry environment causes a more marked response than does exercising in a warm, humid environment. Finally, endocrine factors, such as variations in progesterone and estradiol levels, also influence asthma exacerbations, probably through modification of vagal efferent activity.

Most patients with asthma seem to display an exaggerated bronchoconstrictive response to a variety of exogenous and endogenous stimuli, and inflammation plays a key role. The final common pathway is as follows:

- Airway narrowing
- Bronchial wall edema
- Bronchial smooth muscle contraction
- Mucosal plugging
- Enhanced airway reactivity and remodeling of the airway wall, which results in increased airway resistance
- Decreased forced expiratory volumes and flow rates
- Lung hyperinflation
- Increased work of breathing
- Ventilation-perfusion mismatch

## PRESENTING SIGNS AND SYMPTOMS

When evaluated in the ED, many patients relay a history of asthma, but some do not. Patients with a severe asthma attack may be in obvious respiratory distress, with rapid breathing and loud wheezing, but patients with mild exacerbation may exhibit coughing and end-expiratory wheezing. The classic symptoms of asthma consist of the triad of dyspnea, wheezing, and coughing, but physical findings during an asthma exacerbation can be variable. Early symptoms include a sensation of chest constriction and coughing. As the exacerbation progresses, wheezing becomes apparent, expiration becomes prolonged, and use of the accessory respiratory muscles may become evident. Patients may sit upright or lean forward in an attempt to decrease the work of breathing. Use of the accessory muscles of inspiration indicates diaphragmatic fatigue, whereas the appearance of paradoxic respirations reflects impending ventilatory failure. Alteration in mental status heralds respiratory arrest.

## VARIATIONS IN PRESENTING SIGNS AND SYMPTOMS

Patients with asthma exacerbations may simply exhibit coughing or have a feeling of chest tightness. At the other end of the spectrum are patients with a “silent chest,” which reflects very severe airflow obstruction and air movement insufficient to promote a wheeze.

A subset of asthmatic patients experience a sudden onset of severe symptoms. These individuals tend to respond rapidly to treatment but appear to be at significant risk for a fatal outcome.

## DIFFERENTIAL DIAGNOSIS

Wheezing, coughing, and dyspnea may be cause by many common conditions, including pneumonia, bronchitis, croup, bronchiolitis, chronic obstructive pulmonary disease, congestive heart failure, pulmonary embolism, allergic reactions, and upper airway obstruction from edema or a foreign body. Less common conditions with similar symptoms are cystic fibrosis, hypersensitivity pneumonitis, carcinoid syndrome, and exposure to odors, dust, and gas. A careful history and physical examination should help differentiate asthma from these other conditions.

## DIAGNOSTIC TESTING

As for all patients who come to the ED for care, a directed history and physical examination should be performed. Key historical points should be elicited, such as the duration and onset of the current attack, identification of precipitating causes, type and amount of medications used before arrival at the ED, response to previous therapy, including current or previous use of corticosteroids, frequency of ED visits and hospitalizations, previous need for intubation or ventilation, history of concurrent medications and allergies, and history of concurrent medical problems. At some point during the patient’s ED stay, effort should be made to evaluate both the severity of the obstruction and the adequacy of ongoing asthma control.

The physical examination should focus on observing respiratory effort and use of accessory muscles and listening for wheezing or other abnormal breath sounds and prolongation of the expiratory phase. Although wheezing results from movement of air through narrowed airways, the intensity of the wheeze may not correlate with the severity of airflow obstruction. Tachycardia and tachypnea are usually present in patients with acute asthma, but vital signs normalize very quickly as the airflow obstruction is relieved. Therefore, a normal heart rate and respiratory rate are not reliable indicators of the degree of relief from obstruction.

Bedside spirometry provides a rapid, objective assessment of patients and helps both indicate the effectiveness of and guide therapy. Sequential measurements assist emergency physicians in assessing the severity of the problem and determining the response to therapy. Although forced expiratory volume in 1 second (FEV₁) and the peak expiratory flow (PEF) rate measure the extent of large airway obstruction, patient cooperation is essential for these tests to be reliable. When possible, management decisions should be guided by a patient’s personal best PEF rate or FEV₁ value or, if unknown, a percentage of the predicted value in addition to other physiologic and historical factors.

Pulse oximetry is a useful and convenient method for accessing oxygenation and monitoring oxygen saturation during treatment. Analysis of arterial blood gases is not indicated in the majority of patients with mild to moderate asthma.
exacerbation, but it is helpful if there is concern for hypoventilation with carbon dioxide retention and respiratory acidosis. Patients with the latter problems almost always have clinical evidence of severe attacks or spirometry demonstrating PEF or FEV₁ less than 25% of the predicted value. Practitioners should be aware that a normal or slightly elevated PaCO₂ (e.g., 42 mm Hg or higher) indicates extreme airway obstruction and fatigue and may herald the onset of acute ventilatory failure.

Routine radiography is unnecessary but is indicated if the possibility of pneumothorax, pneumomediastinum, pneumonia, or other medical conditions is a concern. In up to one third of asthmatic patients requiring admission, an abnormality is demonstrated on chest radiographs.

A routine complete blood cell count is not indicated and would probably show modest leukocytosis secondary to the administration of β₂-agonist therapy or corticosteroid treatment. In patients taking theophylline before ED evaluation, a serum theophylline level should be determined. A routine electrocardiogram is also unnecessary; electrocardiographic abnormalities noted include right ventricular strain, abnormal P waves, and nonspecific ST-T wave abnormalities, which resolve with treatment. Older patients, especially those with coexisting heart disease, should undergo cardiac monitoring during treatment. Asthma severity index scores have failed to predict outcome better than clinical judgment does.

Use of exhaled nitric oxide measurements and other serum and urine markers for detection of the severity of the asthma exacerbation is currently under investigation.

### TREATMENT

The goal of treatment of acute asthma in the ED is to rapidly reverse the airflow obstruction with repetitive or continuous administration of inhaled β₂-agonists, ensure adequate oxygenation, and relieve inflammation. The National Asthma Education and Prevention Program Expert Panel has developed guidelines for emergency treatment of asthma as have other organizations around the world. Prehospital treatment with oxygen and β₂-agonists is usually initiated. The following types of medications have been shown to be effective for the treatment of acute asthma: β₂-agonists, anticholinergics, and glucocorticoids. Magnesium should be considered in patients with severe obstruction. Current evidence does not support the use of heliox (helium-oxygen mixture) or ketamine, even when the aforementioned medications fail to relieve bronchospasm. Mast cell–stabilizing agents, methylxanthines, and leukotriene modifiers are currently reserved for maintenance therapy only.

#### PHARMACEUTICALS

**β₂-Agonist Agents**

β₂-Agonists are the preferred initial rescue medications for acute bronchospasm. In addition to bronchodilation, these drugs inhibit the release of mediators and promote mucociliary clearance.

The most common side effect of β₂-agonist drugs is skeletal muscle tremor. Patients may also experience nervousness, anxiety, insomnia, headache, hyperglycemia, palpitations, tachycardia, and hypertension. Despite earlier concerns about the potential cardiotoxicity of these agents, clinical experience has not revealed significant problems. Arrhythmias and

| Exacerbations may affect activity | | PEF variability 20%-30% |

| **Step 1:** Mild intermittent | | |
| Symptoms < 2 times per week | ≤2 times per month | FEV₁ or PEF ≥ 80% of predicted value |
| Asymptomatic and normal PEFR between exacerbations | | PEF variability < 20% |
| Exacerbations brief (from a few hours to a few days; intensity may vary) | | |

Initial assessment
History, physical examination (auscultation, use of accessory muscles, heart rate, respiratory rate, PEF or FEV, oxygen saturation, and other tests as indicated

FEV1, or PEFR ≥ 40% (mild to moderate exacerbation)
- Inhaled β2-agonist by metered dose inhaler or nebulizer, up to three doses in first hour
- Oxygen to achieve O2 saturation ≥ 90%
- Oral systemic corticosteroids if no immediate response or if patient recently took oral systemic corticosteroid

FEV1, or PEFR < 40% (severe exacerbation)
- Inhaled high dose β2-agonist and anticholinergic by nebulization every 20 minutes or continuously for 1 hour
- Oxygen to achieve O2 saturation ≥ 90%

Impending or actual respiratory arrest
- Intubation and mechanical ventilation with 100% O2
- Nebulizer β2-agonist and anticholinergic
- Intravenous corticosteroid
- Consider adjunct therapies

Repeat assessment
Symptoms, physical examination, PEF, O2 saturation, other tests as needed

Moderate exacerbation
FEV1 or PEFR 40-69% predicted/personal best
Physical exam: moderate symptoms
- Inhaled short acting β2-agonist every 60 minutes
- Systemic corticosteroid
- Continue treatment 1-3 hours, provided there is improvement

Severe exacerbation
FEV1 or PEFR < 40% predicted/personal best
Physical exam: severe symptoms at rest, accessory muscle use, chest retraction
History: high-risk patient
No improvement after initial treatment
- Inhaled short-acting β-agonist, hourly or continuous + inhaled anticholinergic
- Oxygen
- Systemic corticosteroid
- Consider adjunct therapies

Good response
- FEV1 or PEFR ≥ 70%
- Response sustained 60 minutes after last treatment
- No distress
- Physical exam: normal

Incomplete response
- FEV1 or PEFR 40-69%
- Mild to moderate symptoms

Poor response
- FEV1 or PEFR < 40%
- PCO2 ≥ 42 mm Hg
- Physical exam: symptoms severe, drowsiness, confusion

Individualized decision regarding hospitalization (see text)

Discharge home
- Continue treatment with inhaled β-agonist
- Consider treatment with inhaled corticosteroids
- Continue course of oral systemic corticosteroid
- Patient education
  - Review medicine use
  - Review/initiate action plan
  - Recommend close medical follow-up

Admit to observation unit or hospital ward
- Inhaled β2-agonist
- Systemic (oral or intravenous) corticosteroid
- Oxygen
- Monitor FEV1 or PEF, O2 saturation, pulse

Admit to hospital intensive care
- Inhaled β2-agonist hourly or continuously
- Intravenous corticosteroid
- Oxygen
- Consider adjunct therapies
- Possible intubation and mechanical ventilation

Contains EDTA to prevent discoloration This additive does not induce bronchospasm

Continued
evidence of myocardial ischemia are rare, especially in patients without a previous history of coronary artery disease.

Aerosol therapy with β₂-agonist drugs produces excellent bronchodilation with minimal systemic absorption and few side effects. Aerosol delivery may be achieved with a metered dose inhaler (MDI) with a spacing device or a compressor. Side effects of corticosteroids is delayed at least 4 to 8 hours after intravenous or oral administration.

Data indicate that corticosteroids, administered within 1 hour of arrival in the ED, reduce the need for hospitalization of a patient with an asthma exacerbation. Although evidence for what constitutes the optimal dose for acute asthma is lacking, experts agree that an initial 40- to 60-mg dose of prednisone or an intravenous 60- to 125-mg bolus of methylprednisolone in patients unable to tolerate oral medications is usually adequate. No advantage has been demonstrated for higher doses. Additional doses should be given every 4 to 6 hours until significant subjective and objective improvement is achieved. Patients who are being discharged home after ED treatment should be prescribed a 3- to 10-day nontapering “burst” of oral steroids, such as prednisone, 40 to 60 mg/day, or its equivalent.

Current recommendations favor inhaled corticosteroids for maintenance of all patients with mild persistent asthma or more severe asthma. Therefore, consideration should be given to discharging any patient with mild persistent or more severe asthma with maintenance inhaled corticosteroid therapy in addition to the burst of oral steroids.

**Anticholinergics**
Aerosolized ipratropium bromide, 0.5 mg, should be administered to patients with a severe exacerbation of asthma. Ipratropium is a synthetic quaternary derivative that is available as both a nebulized solution and in an MDI (18 mg per puff) and is well tolerated (see Table 48.2). Clinical trials indicate that adding ipratropium to β₂-agonist agents offers mild additional improvement in bronchodilation and significantly decreases the need for hospitalization. Side effects include dry mouth, thirst, and difficulty swallowing. Less commonly, tachycardia, restlessness, irritability, confusion, difficulty in micturition, ileus, blurring of vision, and an increase in intraocular pressure are noted.

*Children younger than 12 years.

†Note: No advantage has been found for higher-dose corticosteroids for severe asthma exacerbations, nor does intravenous administration have any advantage over oral therapy, provided that gastrointestinal transit time or absorption is not impaired. The usual regimen is to continue the frequent multiple daily doses until the patient achieves a forced expiratory volume in 1 second or PEF of 50% of the predicted value or the patient’s personal best—which usually occurs within 48 hours—and then to lower the dosage to twice daily. Therapy after a hospitalization or ED visit may last 3 to 10 days. For corticosteroid courses lasting 1 week or less, there is no need to taper the systemic corticosteroid dose. For slightly longer courses (e.g., up to 10 days), there is probably no need to taper, especially if patients are concurrently taking inhaled corticosteroids. If the follow-up systemic corticosteroid therapy is to be given once daily, one study indicates that it may be more clinically effective to give the dose in the afternoon at 3 PM, with no increase in adrenal suppression.

### Corticosteroids
Corticosteroids, highly effective drugs for asthma exacerbation, are a cornerstone of treatment. They are thought to produce beneficial effects by restoring β₂-agonist responsiveness and reducing inflammation. Onset of the antiinflammatory effects of corticosteroids is delayed at least 4 to 8 hours after intravenous or oral administration.

### Anticholinergics
Aerosolized ipratropium bromide, 0.5 mg, should be administered to patients with a severe exacerbation of asthma. Ipratropium is a synthetic quaternary derivative that is available as both a nebulized solution and in an MDI (18 mg per puff) and is well tolerated (see Table 48.2). Clinical trials indicate that adding ipratropium to β₂-agonist agents offers mild additional improvement in bronchodilation and significantly decreases the need for hospitalization. Side effects include dry mouth, thirst, and difficulty swallowing. Less commonly, tachycardia, restlessness, irritability, confusion, difficulty in micturition, ileus, blurring of vision, and an increase in intraocular pressure are noted.
At discharge, addition of tiotropium to the patient’s current inhaled corticosteroid dose is comparable to the addition of salmeterol—both are more effective in achieving disease control than is doubling the inhaled corticosteroid dose.27

**Magnesium**

Intravenous magnesium sulfate is indicated for the management of acute, very severe asthma, such as a patient with an FEV₁ less than 25% of predicted, but not in those with mild or moderate asthma exacerbation.28-30 The dose is 1 to 2 g intravenously delivered over a 30-minute period. Inhaled magnesium may also be a helpful adjunct in the treatment of a severe exacerbation.31,32 Magnesium is not a substitute for standard therapy regimens.

**Heliox, Ketamine, and Halothane**

Helium is not indicated for use in patients with mild or moderate asthma exacerbation, although several studies have demonstrated its effectiveness for very severe asthma.33 Several investigators have reported success with ketamine34,35 and halothane in patients in whom all other treatment modalities have failed. Controlled trials substantiating these claims are lacking.

**Mast Cell Modifiers**

Neither cromolyn nor nedocromil, both modulators of mast cell mediator release and eosinophil recruitment, is indicated for the treatment of acute bronchospasm.

**Leukotriene Modifiers**

Leukotriene modifiers improve lung function, diminish symptoms, and reduce the need for short-acting β₂-agonists.1 They are recommended as an alternative to low-dose inhaled corticosteroid therapy in patients with mild persistent asthma and as steroid-sparing agents with inhaled corticosteroids in those with moderate persistent asthma. Several leukotriene modifiers—montelukast, zafirlukast, and zileuton—are currently available as oral tablets for the treatment of asthma. Although intravenous montelukast has been demonstrated to cause rapid bronchodilation when used as adjuvant therapy for acute asthma in a single trial, recommending its use for the treatment of acute bronchospasm in the ED would be premature.36 Montelukast, zafirlukast, and zileuton have been associated with neuropsychiatric side effects.

**Theophylline**

Although theophylline is no longer considered a first-line treatment of acute asthma,37 some patients who come to the ED for treatment may be using it at home. Some data suggest that this agent has an antiinflammatory mechanism of action. When used in combination with inhaled β₂-agonists, theophylline appears to increase the toxicity—but not the efficacy—of treatment. The most common side effects of theophylline are nervousness, nausea, vomiting, anorexia, and headache. At plasma theophylline levels greater than 30 mcg/mL, there is a risk for seizures and cardiac arrhythmias.

**MECHANICAL VENTILATION**

When it appears that a patient needs more than the aforementioned treatments, noninvasive positive pressure ventilation may be attempted. Data showing that bilevel positive airway pressure reduces the need for intubation and mechanical ventilation are lacking.38-40

If the patient begins to exhibit signs of acute ventilatory failure with progressive hypercapnia and acidosis or becomes exhausted or confused, intubation and mechanical ventilation are needed to prevent respiratory arrest. Mechanical ventilation can eliminate the work of breathing and enable the patient to rest. It does not relieve the airflow obstruction. Direct, controlled oral intubation by an experienced physician is preferred.

The potential complications of mechanical ventilation in asthmatic patients are numerous: barotrauma, hemodynamic impairment, mucous plugging leading to increased airway resistance, atelectasis, and pulmonary infection. Air trapping and increased residual volume (intrinsic positive end-expiratory pressure) may be partially avoided with controlled mechanical hyperventilation or permissive hypoventilation.39,40 This form of mechanical ventilation is achieved by using a reduced respiratory rate and low inspiratory volume and pressure and allowing adequate time for the expiratory phase. One can achieve the goal of ventilatory support—maintenance of adequate arterial oxygen saturation (90% or greater)—without concern about “normalizing” the hypercapnic acidosis. All patients requiring mechanical ventilation should be admitted to an intensive care unit.

**Priorities Actions**

1. Ensure adequate oxygenation.
2. Reverse airflow obstruction with β₂-agonists.
3. Relieve inflammation by prescribing oral systemic corticosteroids.
4. Monitor response to therapy with serial assessments.

**Disposition**

Disposition decisions for patients after treatment of asthma exacerbation are rarely straightforward. A number of subjective and objective factors should be considered, as follows:

- Does the patient feel that the wheezing and air exchange have improved?
- Does auscultation confirm improvement or lack thereof?
- Has a significant improvement in FEV₁ or PEF been noted?
- What is the patient’s health care history?
- Is the patient usually compliant with care plans and medication regimens?
- Does the patient have access to prompt follow-up?
- Does the patient usually require hospitalization after an exacerbation?

Unfortunately, a formula for successful discharge without risk for early relapse does not yet exist, and up to 25% of patients treated in the ED for asthma return within 3 weeks.41-44 Because some degree of residual airflow obstruction, airway lability, and inflammation persists after treatment and discharge from the ED, a postdischarge treatment plan must be formulated.
Addition of a short, nontapering course of oral steroids to the scheduled use of a β₂-agonist bronchodilator reduces relapse rates in discharged patients. Patients with chronic asthma who are not using controller medications at home should be prescribed and educated about the daily use of either inhaled corticosteroids or leukotriene modifiers, in addition to their rescue medications. Data indicate that relying on the primary care physician to prescribe these controllers at follow-up is inadequate.

Current guidelines suggest that patients with a good response to treatment, as demonstrated by complete resolution of symptoms and a PEF or FEV₁ value greater than 70% of predicted, can be safely discharged home. Patients with a poor response to treatment, as defined by persistent symptoms, a PEF or FEV₁ value less than 50% of predicted, and persistent wheezing and dyspnea at rest, should be admitted. Many patients with an incomplete response to treatment, as defined by some persistence of symptoms and a PEF or FEV₁ value between 50% and 70% of predicted, may be discharged home safely, provided that they have no risk factors for death from asthma. Patients who do not show adequate improvement over several hours because they are in the late phase of the exacerbation and those with significant risk factors for death from asthma should be admitted to either an observation unit or the hospital. Most patients have an incomplete response to treatment and fall into this “gray zone” of disposition decisions.

Studies indicate that the majority of asthmatic patients admitted to an observation unit where strict care protocols are followed can be successfully treated and discharged. Early follow-up care is indicated to monitor resolution of the exacerbation and to review the long-term medication and care plans for the ongoing management of asthma. High relapse rates despite the routine use of steroids strongly suggest the need for follow-up within days of the ED visit. Ideally, education of the patient begins in the ED, and a written plan of action that addresses both routine treatment and care of worsening symptoms is developed either in the ED or at follow-up. ED personnel should provide basic education about asthma and help connect the patient with a primary care provider or asthma specialist while providing discharge instructions. Review of the patient’s discharge medication, evaluation of inhaler technique, and instruction on the use of peak flow monitoring are just some of the issues that emergency physicians can teach and emphasize.

Chronic Obstructive Pulmonary Disease
Craig G. Bates and Rita K. Cydulka

KEY POINTS

- Chronic obstructive pulmonary disease (COPD) is a chronic lung disease with significant societal costs; its prevalence is probably underestimated.
- Acute exacerbations of COPD are usually triggered by respiratory irritants or infections that initiate an inflammatory cascade.
- Emergency department evaluation of potential acute exacerbations must include evaluation for other life-threatening causes of dyspnea such as cardiac ischemia, pneumonia, pulmonary embolism, and congestive heart failure.
- Emergency department management of COPD exacerbation includes oxygen, inhaled bronchodilators, antibiotics, corticosteroids, and in serious cases, noninvasive positive pressure ventilation or intubation.

PERSPECTIVE

Chronic obstructive pulmonary disease (COPD) is a heterogeneous disease that encompasses clinical entities such as emphysema and chronic bronchitis. Although a variety of guidelines have addressed the definition and diagnosis of COPD, a major issue is that most guidelines include a combination of clinical terms and anatomic pathology, which limits their utility for emergency physicians (EPs). The American Thoracic Society defines COPD as a disease state characterized by the presence of airflow obstruction as a result of chronic bronchitis or emphysema. Chronic bronchitis is defined as the presence of a chronic productive cough for 3 months in each of 2 successive years in a patient in whom other causes of chronic cough have been excluded. Emphysema is defined as abnormal permanent enlargement of the air spaces distal to the terminal bronchioles accompanied by destruction of their walls without obvious fibrosis. A potentially more useful definition for EPs comes from the Global Initiative for Chronic Obstructive Lung Disease (GOLD), which states that COPD is a disease state characterized by airflow limitation that is not fully reversible. The limitation in airflow is usually both progressive and associated with an inflammatory response of the lungs to noxious particles or gases, such as tobacco smoke in particular. This definition encompasses chronic bronchitis, emphysema, bronchiectasis, and to a lesser extent, asthma and acknowledges that most patients with COPD have a combination of these different diseases.

EPIDEMIOLOGY

Lack of agreement among definitions of COPD, combined with delayed diagnosis in many patients, makes estimates of prevalence difficult. In 2008, 13.1 million U.S. adults (aged 18 and older) were estimated to have COPD, but close to 24 million U.S. adults have evidence of impaired lung function, thus indicating underdiagnosis of COPD. COPD accounted for 1.5 million emergency department (ED) visits and 726,000 hospitalizations in 2000. In 2010, the cost to the nation for COPD was projected to be approximately $49.9 billion, including $29.5 billion in direct health care expenditures, $8.0 billion in indirect morbidity costs, and $12.4 billion in indirect mortality costs. COPD was the third leading cause of death in the United States in 2007 with 124,477 victims, more than half of whom were female. Of note, the prevalence of COPD in women has doubled in the past few decades but has remained stable in men.

In industrialized countries, 80% to 90% of the risk for COPD is from cigarette smoking. Tobacco smoke is the major risk factor for the development of COPD, but only 15% of smokers experience COPD. Other factors associated with the development of COPD, in addition to smoking, are occupational dust, chemical exposure, and air pollution.

PATHOPHYSIOLOGY

CHRONICALLY COMPENSATED CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The lung reacts to irritants such as tobacco smoke by increasing the number of macrophages and neutrophils in the airways, lung interstitium, and alveoli. In susceptible individuals, these inflammatory cells release proteases that if left unchecked, eventually break down lung parenchyma and stimulate mucus secretion. Cells that normally secrete surfactant and protease inhibitors are replaced by mucus-secreting cells. At the alveolar and bronchiolar level there is loss of elastic recoil caused by tissue destruction, as well as collapse and narrowing of the
smaller airways because of loss of surfactant-producing cells. At the bronchial level, irritants cause pooling of mucus and resultant colonization by bacteria.

**ACUTE EXACERBATIONS**

Acute exacerbations of COPD are usually triggered by an event, such as an infection or other respiratory irritant, that starts an inflammatory cascade. In more than 75% of patients with acute exacerbations an infectious agent is found. In addition, it is likely that up to 50% of acute exacerbations are bacterial in nature. Other important triggers for exacerbation are oxidative stress, lower temperatures, and medications. Beta-blockers, sedatives, and narcotics are the medications that most frequently contribute to exacerbations. Regardless of the specific trigger or triggers, inflammatory mediators cause bronchoconstriction and pulmonary vasoconstriction.

Another aspect of the pathophysiology of acute exacerbation is the potential for acute respiratory acidosis. When high levels of inspired oxygen are administered during management of a COPD exacerbation, the vasoconstriction that normally shunts blood away from inadequately ventilated areas is reversed, thereby leading to worsening ventilation-perfusion mismatch and acute rises in the arterial CO₂ concentration. Contrary to previous dogma, the hypoxic drive in this process is not significantly increased during acute exacerbations, and the majority of the pathophysiologic manifestations result from ventilation-perfusion mismatch.

---

**PRESENTING SIGNS AND SYMPTOMS**

**CLASSIC**

The signs and symptoms in a chronically compensated patient depend largely on the stage of the patient’s disease. Very early in the course of the disease, patients often do not carry the diagnosis of COPD and have subtle findings, such as mild exertional dyspnea and a chronic cough that is frequently identified as a “smoker’s cough.”

Acute exacerbations produce signs and symptoms that represent the impact on multiple body systems. See Table 49.1 for the signs and symptoms of both chronically compensated COPD and acute exacerbations of COPD.

**VARIATIONS**

Because COPD encompasses a wide range of severity of disease, it has a variety of different manifestations. The biggest variations are to be found at the extremes of disease.

Early in the course of the disease, patients may simply have a persistent cough without notable dyspnea. It is important to identify such patients and secure follow-up care. Patients may also note a dry cough that is triggered by deep breaths and may or may not be associated with wheezing and dyspnea. This symptom suggests an episode of bronchitis that could be an exacerbation of underlying lung disease in at-risk patients.

Patients in the late stages of COPD pose a new set of challenges. Those with significant airway obstruction may not

generate enough air movement to wheeze and have a “silent chest.” Such patients need aggressive management to avoid progressive respiratory failure. Patients with a significantly enlarged chest from emphysematous changes may be difficult to auscultate. Finally, patients with severe hypoxemia or hypercapnia (or both) may have primarily symptoms of altered mentation.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of acute dyspnea is quite large. Because many of these conditions are life-threatening, it is critical to differentiate between them so that appropriate treatment can be initiated.

The EP must resist the temptation to automatically diagnose COPD as the sole cause of dyspnea in a patient with a history of COPD. Patients with COPD frequently have serious comorbid conditions that may be unrecognized and play a role in their ED visit. It is also important for the EP to continue to keep an open mind to the possibility of alternative diagnoses, particularly if the patient is not showing the expected response to standard treatment of COPD.

**ASTHMA**

Asthma and COPD coexist in some patients, and both diseases involve the presence of airway obstruction, with some key differences. In the ED setting the key point is that the initial stabilizing actions for severe manifestations of either disease do not vary greatly.

**CONGESTIVE HEART FAILURE**

Congestive heart failure (CHF) can pose a significant diagnostic challenge for EPs because it can be manifested similar to other causes of acute dyspnea and also coexists with other chronic causes of dyspnea such as COPD. Patients with a history of both conditions and acute dyspnea may have exacerbations of one or even both conditions at the same time.

Historical elements are minimally helpful in discriminating among patients. Although studies indicate that the presence of orthopnea (likelihood ratio [LR] = 2.0) and dyspnea with exertion (LR = 1.3) is more commonly associated with CHF, both symptoms are common in either disease.

Physical examination can be of some assistance in clarifying the differentiation between CHF and COPD. The presence of jugular venous distention is helpful in pointing toward the differentiation between CHF and COPD. The presence of orthopnea (likelihood ratio [LR] = 2.0) and dyspnea with exertion (LR = 1.3) is more commonly associated with CHF, both symptoms are common in either disease.

The chest radiograph is most useful in patients with evidence of significant interstitial edema. Absence of this finding does not rule out CHF; however, because patients with chronic lung disease are less likely to have the classic chest radiographic findings of CHF.

The brain natriuretic peptide (BNP) assay shows great promise in assisting in making the diagnosis of CHF. In one study it was more accurate than any other single variable (including the history, physical examination, chest radiographs, and electrocardiogram) in determining whether CHF was present. It is most helpful if the value is very high (>500 pg/mL) or very low (<100 pg/mL). A number of disease states other than CHF can cause elevation of the BNP value; in particular, the presence of COPD with associated cor pulmonale elevates the BNP value to a lesser degree than does left-sided failure. Be aware that obesity can falsely decrease a BNP value.

**PULMONARY EMBOLISM**

The diagnosis of pulmonary embolism (PE) must be considered in any dyspneic patient, particularly when risk factors for venous thromboembolism are present. There is evidence that 25% of patients with a severe COPD exacerbation of unknown origin actually have PE. Key risk factors include older age, recent surgery or trauma, previous venous thromboembolism, hereditary thrombophilia such as factor V Leiden, malignancy, smoking, and use of estrogen-containing hormone replacement therapy. The classic manifestation of PE—pleuritic chest pain, dyspnea, tachycardia, and hypoxia—is not frequently encountered in the ED, but at least one of these elements is almost always present. Some historical clues to possible PE are a sudden onset of symptoms and syncope or near syncope in combination with the risk factors listed previously.

Physical examination offers no clues to the diagnosis of PE in 28% to 58% of patients. The diagnosis is based on a combination of the initial clinical impression of a patient’s risk level and the results of additional testing such as pulmonary imaging. Patients with significant underlying asthma or COPD are frequently not good candidates for ventilation-perfusion scans because preexisting ventilation and perfusion abnormalities will reduce the utility of the test by increasing the likelihood of an intermediate-probability result. D-dimer testing may be of some assistance in patients with a sufficiently low pretest probability, as determined by various clinical decision rules in the literature. The EP must be aware of the many disease processes that cause false-positive results and make the utility of D-dimer assay questionable in many acutely ill patients. It is of highest utility in a population that is at low risk for PE and has a lower severity of symptoms, and it is unlikely to include patients with an exacerbation of COPD.

**ACUTE CORONARY SYNDROME**

Dyspnea can be the main complaint in patients with acute coronary syndromes. Among elderly patients with a diagnosis of acute coronary syndrome in the Global Registry of Acute Coronary Events (GRACE), dyspnea was the dominant symptom in 49.3%. An electrocardiogram should be obtained in all patients seen in the ED with significant dyspnea. Patients with underlying coronary artery disease may have elevations in cardiac biomarkers simply from cardiac myonecrosis secondary to hypoxia. Clinical judgment will guide further cardiac evaluation.

**PNEUMOTHORAX**

COPD is a risk factor for spontaneous pneumothorax, and the primary diagnostic tool is the chest radiograph. The EP should also look for clinical clues, such as asymmetric chest wall excursions and asynchrony in breath sounds or, in more severe cases, tracheal deviation and hemodynamic instability.
PNEUMONIA

Pneumonia commonly coexists with a COPD exacerbation. Clues such as the presence of fever and asymmetric rales on chest auscultation are helpful, but the chest radiograph remains the most useful tool for this diagnosis. The EP should be wary of the accuracy of temperatures taken orally in patients with tachypnea.25

DIAGNOSTIC TESTING

HISTORY

The history should focus on determining the severity of disease to predict critical outcomes, such as the need for admission and mechanical ventilation. Key historical elements include fever, changes in sputum production, hemoptysis, exercise tolerance, orthopnea, current medications, and compliance with medications. The EP should remember to consider key elements of the differential diagnosis while taking the history and should remain alert for alternative causes of the patient’s dyspnea. The presence of symptoms such as chest pain and leg swelling and clarification of how acute in onset the symptoms were will help include or exclude other life-threatening diseases. Important historical questions to ask patients with possible COPD for the purpose of risk stratification are listed in Box 49.1.

PHYSICAL EXAMINATION

On entering the room, the EP should observe the patient’s overall level of distress and body position. Patients with significantly increased work of breathing or in the tripod position should undergo immediate and aggressive intervention.

The patient’s respiratory rate should then be assessed; very high or very low respiratory rates are ominous. Next, the patient’s use of accessory muscles and the proportion of the expiratory phase during breathing should be evaluated. The expiratory phase will lengthen in direct proportion to the degree of airway obstruction. The length of the patient’s sentences provides a simple method of determining the severity of the illness and can be used for more objective reassessment after treatment is initiated.

Assessment of the patient’s overall mental status should follow. Before being spoken to, does the patient appear awake and alert or drowsy? When asked questions, does the patient respond quickly and do the answers make sense? Mental status is an important clue to the level of hypoxia or hypercapnia present.

Next, the EP should observe movement of the chest wall. Is it symmetric? Is there evidence of abdominal breathing, or are retractions present? On auscultation, are wheezes, rales, or rhonchi apparent, and where are they located? The EP should be wary of a “silent chest,” which implies poor air movement. Wheezing can occur as a result of CHF, and asymmetric auscultation findings suggest other diagnoses, such as pneumothorax and pneumonia.

The remainder of the physical examination should focus on findings that suggest alternative diagnoses. The EP should seek signs of CHF, such as gallop rhythms, jugular venous distention, and symmetric lower extremity edema. Asymmetric lower extremity edema and calf tenderness would suggest deep vein thrombosis.

IMAGING AND LABORATORY TESTING

Chest Radiographs

Chest radiographs should be obtained in all patients with anything but a very mild acute exacerbation of COPD. Evidence has shown that clinical criteria are unreliable in accurately predicting the need for radiography.26 The chest radiograph provides valuable information about alternative diagnoses, such as pneumonia, CHF, pneumothorax, and aortic dissection.27

Pulse Oximetry

Pulse oximetry provides a simple and noninvasive method of monitoring hypoxemia in patients with exacerbations of COPD. Pulse oximeters provide accurate estimates of PaO2 (arterial partial pressure of oxygen), as long as the SaO2 (arterial oxygen saturation) value is greater than approximately 90%; with an SaO2 value below this level, the hemoglobin-oxygen dissociation curve becomes quite steep and the correlation is far less reliable. Evidence indicates that an SaO2 value of 92% correlates with a PaO2 value of greater than 60 mm Hg.27

Arterial Blood Gas Analysis

Arterial blood gas (ABG) measurements are not routinely required for COPD exacerbations, although they can be helpful in patients with altered mental status, severe distress, or acidosis. ABG analysis can be helpful for estimating the severity of exacerbations or predicting the future need for mechanical ventilation or bilevel positive airway pressure (BiPAP).28 Patients with simultaneous hypoxemia and hypercapnia are at greatest risk for the development of respiratory failure. It is important to remember that the decision to initiate mechanical ventilation should be based on clinical grounds and not be delayed to obtain ABG results. ABG values can provide clues to questions about issues such as patient fatigue but can never replace the decision-making ability of an experienced EP.

Venous blood gas values may be used to screen for hypercapnia. Although correlation between arterial and venous pH is good, agreement for PCO2 (partial pressure of carbon
dioxide) is only fair. Data indicate that venous PCO$_2$ is 5.8 mm Hg higher than arterial PCO$_2$, but the confidence interval was wide and the correlation was not consistent. This same study indicated that when a cutoff of 45 mm Hg is used, venous blood gas measurements are 100% sensitive and 57% specific in detecting hypercapnia.\textsuperscript{29}

**Spirometry**

Unlike the case with asthma, spirometry is not of significant utility in assessing acute exacerbations of COPD. Spirometry in patients with COPD is most useful in the primary care setting to monitor disease progression over time. Its use in diagnosing or assessing acute exacerbation is not recommended by either the American College of Physicians or the American College of Chest Physicians. Forced expiratory volume in 1 second (FEV$_1$) is only weakly correlated with PCO$_2$ and pH and has no correlation with arterial PO$_2$ in acute exacerbations.\textsuperscript{30} Although many ED studies use spirometry to track clinical changes in patients with COPD, it is important to realize that doing so may provide an incomplete picture of patient status.

**Additional Laboratory Testing**

No data support or refute the use of routine laboratory testing such as a complete blood count or serum chemistry panels in patients with exacerbations of COPD. The need will be dictated mainly by the potential alternative diagnoses, such as CHF or pneumonia. A serum chemistry panel is helpful if an ABG measurement has been ordered. ABG analysis provides a more reliable bicarbonate measurement for clarifying the acuity of respiratory acidosis and in addition assists in diagnosing other acid-base disorders that may be present. A serum chemistry panel should also be ordered in patients complaining of vomiting or weakness and in patients who are taking diuretics or have a history of renal failure. Because of the frequently significant comorbid conditions present in patients with COPD who are sick enough to require admission, laboratory tests for cardiac biomarkers and BNP are often indicated. Other indications for testing are discussed in the section on differential diagnosis.

**INTERVENTIONS, PROCEDURES, AND TREATMENT**

ED goals for treating acute exacerbations of COPD are as follows:

- Rule out other life-threatening causes of dyspnea.
- Ensure adequate oxygenation and ventilation.
- Manage reversible airway obstruction.
- Treat any infectious component of the exacerbation.
- Determine appropriate patient disposition.
- Provide a discharge plan of care that will minimize the risk for recurrences.

A concise summary of the ED management of acute exacerbations of COPD can be found in Table 49.2, and key indicators of severe disease are described in the Red Flags box. The rest of this section supplies additional detail on the different components of management.

**RED FLAGS**

<table>
<thead>
<tr>
<th>Indicator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Worse than the patient’s typical exacerbation of chronic obstructive pulmonary disease</td>
<td></td>
</tr>
<tr>
<td>Significant hypoxia (i.e., SaO$_2$ &lt; 92%) with a typical home O$_2$ flow rate</td>
<td></td>
</tr>
<tr>
<td>Drowsiness or confusion—probable secondary to hypoxia or hypercapnia</td>
<td></td>
</tr>
<tr>
<td>Silent chest—indicative of poor air movement and potential impending respiratory failure</td>
<td></td>
</tr>
</tbody>
</table>

**OXYGEN**

Appropriate use of supplemental oxygen is a key component of management of COPD exacerbations. Oxygen has a number of benefits during exacerbations, including relief of pulmonary vasoconstriction, decrease in right heart workload, and reduction of myocardial ischemia. The effects on the heart allow an increase in oxygen delivery to tissues above and beyond simple rises in hemoglobin oxygen saturation.

The challenge is to maintain appropriate oxygenation while not provoking acute CO$_2$ retention. For most patients, targeting an oxygen saturation value of just over 92% (a reasonable surrogate for a PO$_2$ value of 60 mm Hg) provides a good balance between these two issues.\textsuperscript{3} Whether this saturation value is maintained with oxygen administered via nasal cannula or a Venturi-type mask is not important as long as the saturation values are closely monitored to avoid delivering too little or too much oxygen.

There is good evidence in the prehospital setting that carefully titrated oxygen delivery results in reduced mortality, hypercapnia, and respiratory acidosis in patients experiencing an acute exacerbation of COPD.\textsuperscript{31}

**INHALED MEDICATIONS**

After oxygen, inhaled β$_2$-agonists and anticholinergics are the primary treatment modality for COPD exacerbations because there is usually a small reversible component of the airflow obstruction.

The prototype β$_2$-agonist for COPD is albuterol, delivered either by nebulizer or by metered dose inhaler (MDI) with a spacer. Side effects include tremor, palpitations, tachycardia, headache, mild hypokalemia, nausea, and vomiting. Evidence has shown that the two delivery methods are probably comparable but that severely dyspneic patients may tolerate nebulized medications better.\textsuperscript{32} Albuterol can be given continuously via nebulizer or intermittently. The American Thoracic Society guidelines advise that β$_2$-agonists may be used every 30 to 60 minutes but that more frequent use or continuous administration is well tolerated and may have some benefit. However, the literature on continuous administration of β$_2$-agonists in the treatment of COPD is limited. Decreasing the treatment interval from 60 to 20 minutes has not been shown to improve FEV$_1$, but patients with a lower starting FEV$_1$ value appear to have more benefit with shorter treatment intervals.\textsuperscript{33} It is important to realize the limitations of the FEV$_1$ value in assessing acute exacerbations; the EP should instead rely on the overall clinical picture to guide treatment. Evidence suggests that 2.5 to 5 mg per dose is adequate for the management of COPD exacerbation.\textsuperscript{34}
Table 49.2 Basic Approach to Acute Exacerbations of Chronic Obstructive Pulmonary Disease

<td>Pulmonary embolism protocol; CT if differential diagnosis in doubt</td>
</tr>
<tr>
<td>Determination of disposition</td>
<td>If good response to therapy with mild exacerbation, consider discharge home For patients with moderate exacerbations, consider admission to observation unit if available Patients with severe illness and/or multiple significant comorbid conditions will probably need hospital admission—use likelihood of need for ventilatory support to guide decision for ICU versus floor Patients requiring NIPPV should be admitted to a closely monitored setting, which in most hospitals means at least a stepdown-level bed</td>
</tr>
</tbody>
</table>

ABG, Arterial blood gas; BNP, brain natriuretic protein; CT, computed tomography; ICU, intensive care unit; MDI, metered dose inhaler; NIPPV, noninvasive positive pressure ventilation.

Ipratropium bromide, a quaternary anticholinergic compound, is delivered either by nebulizer or by MDI with a spacer. Side effects include tremor and dry mouth. Both ipratropium bromide and albuterol have comparable clinical effects, and when used together, these two agents improve clinical outcomes and shorten ED length of stay.35

Long-acting inhaled anticholinergics, such as tiotropium, have no place in the acute management of COPD. This agent has demonstrated better efficacy than ipratropium taken four times daily for the chronic management of COPD.36

CORTICOSTEROIDS

Administration of corticosteroids in the ED, followed by an outpatient course of treatment, improves oxygenation and airflow and decreases the rate of treatment failures.37,38 The current literature supports a longer course of treatment than is traditionally done for asthma. Tapering the dosage over a period of 7 to 14 days most likely sufficiently balances the risks associated with corticosteroid use with the advantage of decreased treatment failures. No evidence has shown that a corticosteroid course longer than 14 days confer added benefits. Despite common practice, no strong clinical evidence has indicated that courses shorter than 14 days require a tapering dose.

Administration of corticosteroids in the ED has not been shown to affect the rate of hospitalization. This finding is probably due to the approximate 6-hour delay before the onset of action of corticosteroids.39 Nevertheless, it is important to administer these medications in the ED as soon as possible and before transferring the patient to an inpatient unit because
doing so will probably decrease the overall length of stay in the hospital.

In patients who can tolerate oral intake, there is probably no advantage to intravenous administration of corticosteroids, but data specifically addressing this clinical question are limited.

**ANTIBIOTICS**

The use of antibiotics for acute exacerbations of COPD is recommended in all current guidelines despite some conflicting evidence regarding their efficacy. Two large systematic reviews showed an overall benefit to antibiotic use, with greater efficacy in more severe exacerbations. Antibiotics shorten the duration of the exacerbation and accelerate recovery of peak expiratory flow rates.

The choice of antibiotic has been studied with particular concern about recent increases in β-lactamase–producing strains of bacteria. There is evidence that newer extended-spectrum quinolones achieve better clinical outcomes at lower overall cost than does nonquinolone therapy in patients at high risk for treatment failure (severe underlying lung disease, more than four exacerbations per year, COPD duration > 10 years, elderly, and significant comorbid illnesses). There is also evidence that newer antibiotics, such as macrolides, quinolones, and amoxicillin-clavulanate, are associated with lower hospitalization and clinical failure rates while costing less overall than older antibiotics such as cephalosporins and trimethoprim-sulfamethoxazole. When selecting an antibiotic, factors such as previous antibiotic treatment in the past 3 months, severity of illness, and community resistance patterns must be taken into account.

The ideal duration of antibiotic treatment is not clear. Data suggest that 5 days of antibiotic treatment is probably sufficient, but studies on the optimal duration of treatment with extended-spectrum macrolides and quinolones are lacking.

**METHYLXANTHINES**

Despite a number of guidelines that still recommend their use, methylxanthines such as aminophylline are of no significant benefit to patients with acute exacerbations of COPD and should not be used. It is useful, however, to measure methylxanthine drug levels in patients who are already taking them on an outpatient basis.

**NONINVASIVE POSITIVE PRESSURE VENTILATION**

Noninvasive positive pressure ventilation (NIPPV) involves the application of positive pressure ventilation via face mask and is associated with significantly fewer complications than the case with endotracheal intubation and mechanical ventilation. NIPPV can be applied in one of two modes, continuous positive airway pressure (CPAP) or BiPAP. Both modes can have oxygen bleeding into the system.

CPAP delivers a continuous level of positive pressure throughout the respiratory cycle and is analogous to positive end-expiratory pressure (PEEP) in mechanical ventilation. CPAP improves respiratory mechanics by increasing mean airway pressure, improving functional residual capacity, and opening underventilated and collapsed alveoli. The overall effect is to enhance gas exchange and oxygenation. CPAP is usually initiated at a low level and titrated upward to a typical maximum of 15 cm H₂O to allow adequate oxygenation with as low an FIO₂ (fraction of inspired oxygen) value as possible.

BiPAP provides different levels of positive airway pressure for inspiration (IPAP) and expiration (EPAP). This is analogous to pressure support and PEEP in mechanical ventilation. BiPAP provides the same benefits of continuously applied positive pressure as CPAP does but also theoretically reduces the work of breathing by providing a pressure boost for inspiration. BiPAP can be time-triggered to a certain number of breaths per minute or flow-cycled to allow the patient to trigger the device. IPAP is generally started at approximately 8 cm H₂O and titrated upward to a typical maximum of 20 cm H₂O. EPAP is generally started at approximately 4 cm H₂O and titrated upward to a typical maximum of 15 H₂O. The settings should be balanced to allow physiologic tidal volumes (5 to 7 mL/kg) and maximal oxygenation with a minimum FIO₂ while still maintaining patient comfort.

To be successful candidates for NIPPV, patients must be alert, breathing spontaneously, and able to cooperate with instructions (Box 49.2). This modality can be used with extreme care in patients with mild decreases in level of consciousness. A good rule of thumb is that patients who cannot constantly keep their head up independently will not probably succeed with NIPPV. Adequate staffing levels, continuous monitoring of the heart rate and pulse oximetry, and intermittent blood pressure measurements are essential for safe and successful use of NIPPV. NIPPV is most likely to be successful when a partnership exists among the patient, nursing staff, respiratory therapist, and physician that involves effective communication in all directions before and during the initiation of treatment. It is also most likely to be successful if initiated early in the patient’s stay in the ED.

As with mechanical ventilation, the EP must be alert for hemodynamic changes and desaturations that may indicate loss of mask seal, intrinsic PEEP (also called auto-PEEP), pneumothorax, and patient intolerance. Gastric distention with resultant restriction of diaphragmatic excursion or vomiting is another potential complication of NIPPV. Contraindications to NIPPV are altered mental status, impaired airway protection mechanisms, apnea, cardiovascular instability, and pneumothorax. In addition, any craniofacial abnormality (e.g., previous surgery, trauma) that impairs the ability to obtain a reliable mask seal would preclude NIPPV.

**BOX 49.2 Indications for Use of Noninvasive Positive Pressure Ventilation (NIPPV)**

NIPPV should be considered in patients with the following clinical features as long as the contraindications previously discussed are not present:

- Difficulty maintaining oxygen saturation greater than 90% with a nonrebreather mask
- Moderate to severe dyspnea
- Respiratory rate greater than 25 breaths/min
- Moderate respiratory acidosis (pH of 7.30 to 7.35)
- Sufficient alertness to hold one’s own head upright and follow commands
In patients with COPD, NIPPV has been shown to significantly decrease both the need for intubation and overall patient mortality and to generate significant improvements in pH, Pco₂, and respiratory rate. The delivery method (CPAP versus BiPAP) has not been shown to make a significant difference in outcomes.

**ENDOTRACHEAL INTUBATION AND MECHANICAL VENTILATION**

The decision to intubate a patient with COPD is based largely on clinical judgment and experience. Some patients obviously need intubation (respiratory arrest, decline with NIPPV), but in other patients the need is far less apparent. As mentioned previously, ABG values can assist in the decision to intubate, but the ultimate decision must always be based on clinical assessment. Intubation decisions should not be delayed in critically ill patients to wait for ABG results. General guidelines are available to assist in this decision-making process, but they are just tools that will not make the final decision, and some of the guidelines are vague; they are listed in Box 49.3.

Once the EP has determined that a patient with COPD requires intubation, a few special considerations should be borne in mind. In general, the largest tube that can fit safely between the vocal cords should be used (8 to 8.5 in men, 7.5 to 8 in women) to decrease overall airway resistance. The EP must also carefully consider the expected difficulty of intubation before administering paralytic agents. Effective bag-valve-mask ventilation can be difficult in patients with COPD because of higher airway resistance and lung hyperinflation. Other potential comorbid conditions such as obesity can also make intubation difficult. Patients with COPD are commonly difficult to preoxygenate adequately, a feature that significantly reduces the time available for direct laryngoscopy. Even in a patient who is known to require intubation, NIPPV combined with supplemental oxygen can be helpful in maximizing the effectiveness of preoxygenation. Consider an “awake” look with a combination of topical anesthesia of the airway and light sedation before using full rapid-sequence intubation, particularly in patients in whom intubation may be difficult. Ketamine in initial doses of 0.5 to 1 mg/kg intravenously has some properties that make it an attractive option in this situation because it preserves the airway protection reflexes and also has bronchodilatation properties. Additional doses can be given as necessary. Ketamine can stimulate the sympathetic nervous system, so it should be used with caution in patients with significant coronary artery disease. Other options include benzodiazepines and propofol, but these agents often cause respiratory depression at sedative doses. A full discussion of these issues is outside the scope of this chapter.

Management of hypotensive episodes in patients recently intubated for COPD is the same as that for other intubated patients, but some causes are more common in COPD. Note that patients with NIPPV can exhibit similar issues. See Table 49.3 for additional information.

**DISPOSITION AND FOLLOW-UP**

The decision to admit or discharge a patient with exacerbation of COPD is multifactorial and involves issues that may not be clinical. The response to ED management is the most useful indicator of disposition. EPs must consider whether the patient will be able to receive the maintenance care necessary at home; that is, outpatient management will almost certainly fail in a patient with an oxygen requirement who was not already receiving oxygen. Clinicians must also estimate the probable clinical course: is this patient showing a clear trend toward improvement, or is the course in doubt? The availability of rapid and reliable follow-up care can allow safe discharge of potentially sicker patients. Unfortunately, the absence of such care is more frequently encountered in the ED environment; patients whose social issues, such as limited access to care, put them at high risk for a return ED visit should be admitted.

Finally, it is important to emphasize to patients with COPD that they should promptly seek medical attention for...

---

**BOX 49.3 General Criteria for Intubation in Patients with Acute Exacerbations of Chronic Obstructive Pulmonary Disease**

- Severe dyspnea with the use of accessory muscles
- Respiratory rate greater than 35 breaths/min
- Life-threatening hypoxemia (Pao₂ < 40 mm Hg or Pao₂/FiO₂ < 200)
- Severe acidosis (pH < 7.25) and hypercapnia (Paco₂ > 60 mmHg)
- Respiratory arrest
- Somnolence or significant impairment in mental status
- Cardiovascular complications (hypotension, shock, heart failure)
- Other complications (metabolic abnormalities, sepsis, pneumonia, pulmonary embolism, barotrauma, massive pleural effusion)
- Failure of noninvasive positive pressure ventilation

**Table 49.3 Causes and Treatment of Hypotension After Initiation of Positive Pressure Ventilation in Patients with Chronic Obstructive Pulmonary Disease**

<table>
<thead>
<tr>
<th>CAUSE</th>
<th>TREATMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tension pneumothorax</td>
<td>Needle decompression with a large-bore Angiocath</td>
</tr>
<tr>
<td>Reduced venous return from auto-PEEP (positive end expiratory pressure)</td>
<td>Remove the patient from ventilator Squeeze the chest Adjust the ventilator settings to allow sufficient exhalation time between breaths Fluid boluses to augment preload</td>
</tr>
<tr>
<td>Reduced sympathetic drive</td>
<td>Use smaller doses of sedative medications and fluid boluses to augment preload; rarely is the use of vasopressors is needed</td>
</tr>
</tbody>
</table>

The best treatment is anticipation of potential issues—many patients requiring intubation for exacerbations of chronic obstructive pulmonary disease will require preintubation consideration for all these conditions. All patients being intubated should have a fluid bolus ready for rapid administration through a freely flowing intravenous line if needed.
worsening respiratory symptoms. Patients who wait longer than 24 hours before seeking medical attention are more than twice as likely to require admission regardless of what home care was administered.48

Patients at higher risk for relapse need more careful discharge planning that includes reliable follow-up (Box 49.4).

**BOX 49.4 Risk Factors for Relapse Within 2 Weeks of an Emergency Department (ED) Visit**

Evidence has shown that the following factors place patients at higher risk for relapse within 2 weeks after an ED visit:
- Number of ED or clinic visits in the past year (>5 visits)
- Amount of limitation in activity before arrival
- Initial respiratory rate higher than 16 breaths/min
- Patients who were taking oral corticosteroids before arriving at the ED

REFERENCES

Pneumonia is one of the most common infectious diseases encountered in the emergency department (ED), with more than 1.5 million visits for this infection annually. When combined with influenza, pneumonia ranks as the sixth leading cause of death in the United States and the most common cause of infection-related mortality. Pneumonia is typically defined as an infection of the lung parenchyma with associated symptoms of cough, fever, and abnormal breath sounds on physical examination. Usually an infiltrate is seen on chest radiographs.

Because of the many potential pathogens causing this disease, a thorough history and physical examination are very important in guiding selection of the appropriate empiric antibiotic coverage in patients with pneumonia.

PATHOPHYSIOLOGY

The lungs are constantly exposed to potential pathogens by both organisms in inspired air and those living in the oropharynx and upper respiratory tract. As a result of multiple layers of defense, the lower respiratory tract usually remains sterile. Many protective mechanisms—the cough and gag reflexes, upper airway particle filtration, proper mucociliary clearance, and humoral and cellular immunologic defenses at the alveolar level—play an important role in guarding the lungs against infection.

Pneumonia typically occurs when the protective defenses just described are breached and the lungs are exposed to a heavy inoculation of organisms or to very virulent organisms. The lung’s defenses can be impaired at multiple levels. Aspiration can result when altered levels of consciousness secondary to a neurologic insult or alcohol or drug intoxication impair the gag reflex. The upper airway defenses are often bypassed by endotracheal tubes or tracheostomy. Smoking and chronic lung disease can impair mucociliary function. Bronchial obstruction secondary to tumor or lymphadenopathy can lead to obstruction and pneumonia. Immunologic impairment as a result of infection with human immunodeficiency virus (HIV), chemotherapy, splenectomy, or advanced age also predisposes to pneumonia. The elderly are particularly vulnerable because of impairments at many of these levels and a higher incidence of comorbid conditions (Fig. 50.1).

PRESENTING SIGNS AND SYMPTOMS

The classic symptoms of pneumonia are fever, cough, purulent sputum, and shortness of breath. Patients may also have several nonrespiratory symptoms such as sweats, chills, confusion, headache, fatigue, abdominal pain, nausea, and myalgias. Infants may have decreased oral intake, lethargy, and apnea. Patients of advanced age are less likely to have typical symptoms, instead often exhibiting only weakness or altered mental status.

A goal-directed, comprehensive history is very important in the evaluation of a patient with pneumonia. Historical clues such as risk for aspiration, recent travel, animal or environmental exposure, HIV status or risk, alcoholism, and comorbid illnesses can point toward specific causes and guide the proper choice of initial empiric therapy (Table 50.1). care should be taken to identify patients at risk for health care–associated pneumonia (HCAP), such as recent health care and antibiotic exposure, which could predispose them to multidrug-resistant pathogens and alter treatment choices.\textsuperscript{3}

RED FLAGS

Look for key clues in the history and physical findings that would suggest pneumonia caused by an unusual or resistant organism.

Identify patients at risk for health care–associated pneumonia.

Maintain high suspicion for aspiration pneumonia in the elderly and in patients with altered mental status or a recent cerebrovascular accident.

PATHOGENS

Community-acquired pneumonia is often defined as pneumonia in a patient who has not been hospitalized and has not resided in a long-term care facility for more than 14 days before the appearance of symptoms.\textsuperscript{3} With the growing prevalence of mixed-organism infections, drug-resistant pathogens, and patients with comorbid illnesses, this definition has become somewhat more complicated. Guidelines from the American Thoracic Society (ATS), Centers for Disease Control and Prevention, and Infectious Diseases Society of America (IDSA) now address the treatment of patients at increased risk for pseudomonal infection, those with significant comorbid conditions, and those at risk for infection with drug-resistant \textit{Streptococcus pneumoniae}.

The most common etiologic agent causing pneumonia is \textit{S. pneumoniae}, which is responsible for about two thirds of all cases (Table 50.2).\textsuperscript{3} Other bacterial pathogens that are often isolated are \textit{Mycoplasma pneumoniae}, \textit{Chlamydia pneumoniae}, \textit{Haemophilus influenzae}, and \textit{Legionella pneumophila} (often called “the atypical organisms”). Community-acquired pneumonia is also caused by several viruses, including influenza, parainfluenza, and respiratory syncytial virus (RSV). Other pathogens, such as \textit{Pseudomonas aeruginosa}, drug-resistant \textit{S. pneumoniae}, and methicillin-resistant \textit{Staphylococcus aureus} (MRSA), should additionally be considered in patients who have had recent health care exposure or have recently taken broad-spectrum antibiotics. Multiple other organisms may be considered based on a history of specific exposures, travel, and lung or immunosuppressive diseases.

SPECIAL POPULATIONS

CHILDREN

Pneumonia and acute bronchiolitis are the most common lower respiratory tract infections in children. They are caused by a variety of viruses and bacteria, with the prevalence varying by age group\textsuperscript{5,6} (Table 50.3). As in adults, \textit{S. pneumoniae} is the predominant organism causing pneumonia except in newborns, in whom group B streptococci and gram-negative bacilli dominate. \textit{H. influenzae} type B remains an important bacterial pathogen causing pneumonia in the developing world. It has nearly been eliminated in the United States through immunization practices. Pneumococcal vaccines also appear to be lowering the incidence of invasive pneumococcal disease and pneumonia, but more data are needed.\textsuperscript{11} Many viruses, mainly influenza, parainfluenza, and RSV, can also cause pneumonia in children. Most children with pneumonia have cough, fever, and abnormal lung findings. Signs of tachypnea and increased work of breathing are often present and may be the only signs of disease in infants.\textsuperscript{9}

Acute bronchiolitis is typically caused by RSV or parainfluenza viruses and predominantly affects children younger than 2 years. It can be difficult to distinguish from pneumonia because the clinical features are similar. Bronchiolitis is seasonal, with frequent occurrence in the winter and early spring months. Affected infants typically exhibit sneezing, rhinorhea, coughing, wheezing, fever, and even respiratory distress. Chest examination typically demonstrates diffuse fine crackles and expiratory wheezes. Grunting respirations, cyanosis, retractions, and use of accessory muscles are signs of respiratory distress. Antibiotics are not usually indicated in patients with acute bronchiolitis, and treatment is primarily supportive. Bronchodilator therapy with nebulized albuterol or racemic epinephrine may be effective.

Pertussis (whooping cough) is a respiratory tract infection worthy of special mention. Caused by the organism \textit{Bordetella pertussis}, it typically affects young children and adolescents. The incidence of the disease has markedly decreased because of immunization. Pertussis is manifested in three distinct stages. The first (catarrhal) stage consists of a mild cough, conjunctivitis, and coryza lasting up to 2 weeks. The second stage consists of severe paroxysms of coughing, often followed by strong inhalations of air, which produces the

characteristic “whoop.” This stage can last up to 4 weeks. The
third (convalescent) stage consists of a chronic cough. The
disease is important to identify because multiple complications
can occur, such as complete airway obstruction, secondary
pneumonia, seizures, and encephalitis. Treatment is with
oral erythromycin or azithromycin. Close contacts of the
patient should receive prophylactic antibiotics.9

PATIENTS INFECTED WITH HUMAN IMMUNODEFICIENCY VIRUS
Pneumonia is one of the most common serious bacterial ill-
nesses affecting patients infected with HIV. In addition to the
common community-acquired pathogens, patients with HIV
are more susceptible to opportunistic infections with Pneu-
mo-
cystis carinii, pulmonary tuberculosis, and recurrent bacterial
pneumonia. Antibiotic chemoprophylaxis, highly active anti-
rétroviral therapy, and preventive vaccines appear to be sig-
nificantly improving the incidence and the morbidity and
mortality of pneumonia in patients with HIV.12

ASPIRATION PNEUMONIA
Aspiration of oral or gastric contents can occur in the setting
of altered mental status or dysfunctional swallowing reflexes
secondary to neurologic impairment such as stroke. Aspira-
tion is typically “silent,” and therefore a high index of clinical
suspicion is needed for making the proper diagnosis. Aspira-
tion can lead to chemical pneumonitis and bacterial aspiration
pneumonia more than 60% of the time.5 Abscesses and
empyema can occur in more advanced cases. The pathogens
involved are typically those found in the oropharynx. Patients
who have recently been hospitalized or who reside in nursing
homes may be colonized with S. aureus or gram-negative bacilli, which can cause aspiration pneumonia. Treatment
with clindamycin or piperacillin-tazobactam is generally indicated.

INFLUENZA
Influenza is one of the most common and most serious
viral infections causing pneumonia. Influenza usually has
a seasonal occurrence, typically from December to April. Bacterial superinfections can occur with pneumonia caused
by influenza, most commonly with S. pneumoniae or S. aureus. Rapid identification tests are available to assist in
diagnosis. Antiviral therapy with amantadine or rimantadine
(for influenza A) or oseltamivir (for influenza A and B) may
lessen the symptoms and quicken recovery if started within
48 hours of the onset of illness. In spring 2009 a novel influ-
enza A virus (H1N1) spread globally and resulted in the first
influenza pandemic since 1968, with infection occurring
outside the usual influenza season in many parts of the world.13
The pandemic put nearly all health care and public health
institutions to the test and offered valuable lessons in emer-
gency preparedness, virus detection, antiviral treatment, and
immunization.

COMMUNITY-ACQUIRED METHICILLIN-
RESISTANT STAPHYLOCOCCUS AUREUS
MRSA is usually considered a nosocomial pathogen and
accounts for 20% to 40% of all cases of HCAP and ventilator-
associated pneumonia (VAP).14 A new variant with a different
genetic makeup, community-acquired MRSA, has been
observed to cause cases of severe and rapidly progress-
ing community-acquired pneumonia. It is typically seen in
young and previously healthy patients, often with preceding
influenza-like illnesses. Chest radiographs generally reveal
multilobar cavitating infiltrates. Currently, intravenous vanco-
mycin or linezolid is recommended, but the optimal treatment
regimen has yet to be determined and may eventually include
a combination of antibiotics with antibacterial and antitoxin
mechanisms of action.1

SECTION V  THORACIC AND RESPIRATORY DISORDERS

EVALUATION AND DIAGNOSTIC TESTING

Patients with pneumonia should undergo a complete initial assessment of vital signs, including pulse oximetry and evaluation of the respiratory rate.

CHEST RADIOGRAPHS

Most authorities agree that chest radiographs (posteroanterior and lateral if possible) should be obtained in all patients with suspected pneumonia. Radiographs help confirm the diagnosis of pneumonia and provide possible clues to the causative agent (Table 50.4). Radiographs will also demonstrate associated conditions, such as lung abscess, bronchial obstruction, and pleural effusion (Figs. 50.2 to 50.4). Computed tomography may be necessary for further evaluation of complex infiltrates with pleural effusions, suspected masses, or abscesses. Typical radiologic patterns are expected with certain infections (see Table 50.4). It is important to remember that multiple factors, such as age, immune status, hydration status, and underlying lung disease, can alter the radiographic appearance of pneumonia.

SPUTUM STUDIES

Sputum Gram stain and culture should be performed only if a good-quality specimen can be obtained, transported, and processed appropriately. Sputum studies should be strongly considered for severe pneumonia, for suspected MRSA, in

patients with radiographs consistent with *Mycobacterium tuberculosis*, and in patients who are critically ill. Sputum cultures should routinely be ordered in cases of suspected hospital-acquired pneumonia, HCAP, and VAP. In the ED setting, sputum studies may be particularly useful in rapid testing for influenza or RSV in peak seasons to help select appropriate antiviral therapy and avoid unnecessary antibiotic use.

**BLOOD CULTURES**

In a 2005 study of 414 ED patients with pneumonia, Kennedy et al. found that blood culture results rarely altered or altered antibiotic therapy decisions. Resistant organisms requiring a broadening of antibiotic therapy were identified in only 1% of patients. In a 2009 American College of Emergency Physicians clinical policy statement, the committee concluded that routine use of blood cultures has low yield and rarely leads to a change in management or outcome. A more patient-tailored approach has been suggested, with blood cultures being reserved for higher-risk groups such as those admitted to intensive care units (ICUs) with severe pneumonia, immunocompromised status, or significant comorbid conditions.

**OTHER STUDIES**

A complete blood count and basic serum chemistry studies are typically performed in patients admitted with pneumonia. The blood count can identify disorders such as lymphopenia (possibly indicating HIV infection), neutropenia, and anemia and thus help guide appropriate therapy. Electrolyte and glucose abnormalities are often found in patients with pneumonia, and testing for them may provide prognostic information. Measurement of blood urea nitrogen and serum creatinine is important in determining the level of nursing care and appropriate antibiotic dosing for each patient. Urinary studies such as antigen testing for *Legionella* and *S. pneumoniae* may be useful. Bronchoscopy may be considered in patients with HIV, patients who are immunosuppressed, and patients in whom an unusual infection is suspected. Two newer serum biomarkers, C-reactive protein and procalcitoning, may be useful in predicting patients at risk for increased 30-day mortality. In addition, serial measurements of procalcitonin may be useful for guiding the duration of antibiotic therapy. Thoracentesis may be necessary if a pleural effusion is present and freely flowing. Ultrasonography may be beneficial in identifying free-flowing effusions and to guide sampling of the fluid for cell count, cultures, pH, and fluid analysis.

**TREATMENT**

After decisions regarding respiratory, hemodynamic, and ventilatory support, the most important decision in treating patients with pneumonia is selection of timely and appropriate initial antibiotic therapy. Multiple factors, such as suspected causes, severity of illness, recent antibiotic therapy, patient disposition, antibiotic allergies, and comorbid illnesses, contribute to the selection of optimal antimicrobial therapy.

As already described, the ATS and IDSA have issued detailed guidelines for the treatment of community-acquired pneumonia. Several studies have demonstrated lower mortality in hospitalized patients treated with guideline-recommended antimicrobial regimens. In a 2004 study of 420 patients with pneumonia, Mortensen et al. found significantly lower 30-day mortality in patients who received antimicrobial therapy in concordance with the ATS or IDSA guidelines.

The recommendations in the guidelines are summarized in Box 50.1. The guidelines group recommendations according to the site of therapy (outpatient, inpatient, or ICU), severity of disease, comorbid illnesses, and risk for resistant organisms or *Pseudomonas aeruginosa*.

Ideally, antibiotic therapy should be started in the ED as soon as possible after the diagnosis is made. Because pneumonia accounts for approximately 1.7 million hospitalizations per year with an estimated annual cost of more than $9 billion, improving pneumonia care has become a focus of the Joint Commission on Accreditation of Healthcare Organizations and the Centers for Medicare and Medicaid Services. Several defined quality measures (core measures) have been identified, including the use of evidence-based antibiotic choices, timely antibiotic administration, appropriate use of blood cultures before administration of antibiotics, and administration of pneumococcal and influenza vaccines for appropriate patients. Although the validity of some of the measures are questioned by some authorities, these data are publicly reported and adherence with the measures is often a priority for institutions.

**Box 50.1: Priority Actions**

- Provide immediate supplemental oxygen or ventilatory assistance (or both) to patients with suspected pneumonia as needed.
- A mask should be placed over the face of any patient with suspected pneumonia to prevent spread of disease to other patients waiting for evaluation.
- Antibiotic therapy should ideally be initiated in the emergency department as soon as possible after the diagnosis is made.
Outpatient Treatment

1. Previously healthy and no use of antimicrobials within the previous 3 months:
   - A macrolide (strong recommendation; level I evidence)
   - Doxycycline (weak recommendation; level III evidence)

2. Presence of comorbid conditions such as chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancies; asplenia; immunosuppressing conditions or use of immunosuppressing drugs; or use of antimicrobials within the previous 3 months (in which case an alternative from a different class should be selected):
   - A respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin [750 mg]) (strong recommendation; level I evidence)
   - A β-lactam plus a macrolide (strong recommendation; level I evidence)

3. In regions with a high rate (>25%) of infection with high-level (MIC = 16 mcg/mL) macrolide-resistant Streptococcus pneumoniae, consider use of the alternative agents listed above in No. 2 for patients without comorbid conditions (moderate recommendation; level III evidence)

Inpatients, Non-ICU Treatment

A respiratory fluoroquinolone (strong recommendation; level I evidence)
A β-lactam plus a macrolide (strong recommendation; level I evidence)

Inpatients, ICU Treatment

A β-lactam (cefotaxime, ceftriaxone, or ampicillin-sulbactam) plus either azithromycin (level II evidence) or a respiratory fluoroquinolone (strong recommendation; level I evidence)
(for penicillin-allergic patients, a respiratory fluoroquinolone and aztreonam are recommended)

Special Concerns

If Pseudomonas is a consideration:
   - An antipneumococcal, antipseudomonal β-lactam (piperacillin-tazobactam, ceftazidime, imipenem, or meropenem) plus either ciprofloxacin or levofloxacin (750 mg)
   - The above β-lactam plus an aminoglycoside and azithromycin
   - The above β-lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone (for penicillin-allergic patients, substitute aztreonam for above β-lactam) (moderate recommendation; level III evidence)

If community-acquired methicillin-resistant Staphylococcus aureus is a consideration, add vancomycin or linezolid (moderate recommendation; level III evidence)

HEALTH CARE–ASSOCIATED PNEUMONIA

In the current era of shorter hospital stays and expanded home and long-term care facility treatment, the emergency physician frequently encounters patients at risk for HCAP. In 2005, a joint committee of the ATS and IDSA published an additional set of guidelines for the evaluation and treatment of HCAP. They also apply to hospital-acquired pneumonia and VAP. The guidelines emphasize that HCAP can be caused by a wide variety of bacteria, including multidrug-resistant pathogens, gram-negative organisms, and MRSA, and is often polymicrobial. It is recommended that sputum cultures be performed in all patients, before antibiotic therapy if possible. The recommendations for initial empiric antibiotic therapy are summarized in Table 50.5. The commission also recognized the variability in bacterial pathogens from one institution to another and recommended that local microbiologic data be taken into account when selecting antibiotic therapy.18

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Several validated prediction tools can be used to identify patients with pneumonia who are at increased risk for complications and would benefit from inpatient or ICU treatment. These tools evaluate important patient characteristics, such as age, vital signs, radiographic and laboratory data, and comorbid illnesses, and identify patients at increased risk for 30-day mortality.

In 1997 the Pneumonia Patient Outcomes Research Team (PORT)21 published a prediction rule to identify patients at low risk for death from pneumonia within 30 days; it is now known as the PORT criteria or the Pneumonia Severity Index. A 2005 comparison of three prediction guidelines by Aujesky et al.24 found the Pneumonia Severity Index to be most accurate in identifying low-risk and high-risk patients with pneumonia. The system was developed through analysis of data from thousands of patients with community-acquired pneumonia and was validated in more than 50,000 patients. Patients are divided into five classes based on increasing risk for mortality. Class I (mortality, 0.1% to 0.4%) is assigned on the basis of an age of 50 years or younger and key information from the history and physical examination. Other classes are identified with a point system calculated from the presence of historical data and physical and laboratory findings (Box 50.2).23

Class I and class II patients are considered to have very low risk (30-day mortality, <1%) and can probably be treated as outpatients. Many patients in class III (30-day mortality, <2.8%) might also be candidates for outpatient treatment. Patients in class IV or class V are at much higher risk (30-day mortality, 8.5% to 31.1%) and should probably be admitted to the hospital.23,24

*Risks include antimicrobial therapy in the preceding 90 days, current hospitalization of 5 days or longer, high frequency of antibiotic resistance in the institution or community, hospitalization for 2 days or more in the preceding 90 days, residence in a nursing home or extended care facility, home infusion therapy, long-term dialysis within 30 days, home wound care, family member with multidrug-resistant pathogens, and immunosuppressive diseases or therapy.

†MRSA is a risk factor or has a high incidence locally.

**BOX 50.2 Summary of Risk Class Assignment for Patients with Pneumonia Based on the Pneumonia Severity Index (PORT Criteria)**

**Step 1**
Does the patient have one or more of the following features?
- Age > 50 years
- Neoplastic disease
- Congestive heart failure
- Cerebrovascular disease
- Renal disease
- Liver disease
- Altered mental status
- Pulse > 125 beats/min
- Respiratory rate > 30 beats/min
- Systolic blood pressure < 90 mm Hg
- Temperature < 35° C or > 40° C

No: Assign to risk class I.
Yes: Go to Step 2.

**Step 2**
Assign points to the patient’s risk score according to the presence of the following characteristics:

**CHARACTERISTIC** | **POUNTS ASSIGNED**
--- | ---
Age |  
Men | Age in years (1 point for each year)  
Women | Age in years (1 point for each year) – 10  
Nursing home residency | +10  
Coexisting Illnesses |  
Neoplastic disease | +30  
Liver disease | +20  
Congestive heart failure | +10  

**CHARACTERISTIC** | **POUNTS ASSIGNED**
--- | ---
Cerebrovascular disease | +10  
Renal disease | +10  
**Physical Findings** |  
Altered mental status | +20  
Respiratory rate > 30 breaths/ min | +20  
Systolic blood pressure | +20  
< 90 mm Hg |  
Temperature < 35° C or > 40° C | +15  
Pulse > 125 beats/min | +10  
**Laboratory and Radiographic Findings** |  
Arterial pH < 7.35 | +30  
Blood urea nitrogen > 30 mg/ dL | +20  
Sodium < 130 mmol/L | +20  
Blood glucose > 250 mg/dL | +10  
Hematocrit < 30% | +10  
Pao2 < 60 mm Hg or pulse oximetry value < 90% | +10  
Pleural effusion | +10  

**Step 3**
Use the total points accumulated in step 2 to assign the patient to the corresponding risk class, as follows:
- ≤70—class II  
- 71-90—class III  
- 91-130—class IV  
- >130—class V

PORT, Pneumonia Patient Outcomes Research Team.
The British Thoracic Society has also published a prediction tool, CURB-65, to identify patients at high risk for 30-day mortality. Confusion, elevated blood urea nitrogen, elevated respiratory rate, low systolic or diastolic blood pressure, and age older than 65 years are the high-risk variables identified. A simplified version (CRB-65) allows prediction based on clinical variables alone (eliminating blood urea nitrogen) and may be useful in the outpatient setting. A score of 2 or higher predicts increased risk for mortality, and these patients should probably be admitted. ICU admission should be considered for those with a score of 3 or higher.\(^1\)

It must be emphasized that these prediction rules are only guidelines. Many other factors, such as unique comorbid conditions, psychosocial factors, ability to take oral medications, and patient and caregiver reliability, must also be considered in the decision to admit or discharge the patient. Patients demonstrating signs of shock or respiratory distress should be treated in an ICU setting.

### Patient Teaching Tips

Encourage outpatients to finish their course of antibiotics, even if they start to feel better earlier, because not finishing the full course of medicine could lead to incomplete treatment of the infection and clinical relapse.

Because most respiratory infections are spread by means of respiratory droplets, patients with pneumonia should be told to wash their hands frequently, not share utensils or cups, and cover their mouth when coughing to prevent spread of the infection to close contacts. Patient may wish to wear a mask over their mouth and nose when around others who have chronic lung disease or are immunosuppressed.

Patient should be encouraged to return to the emergency department if they experience worsening of symptoms or increasing shortness of breath.
REFERENCES

Pneumothorax

David E. Manthey and Bret A. Nicks

With loss of the normal negative pressure, the affected lung collapses. Primary spontaneous pneumothorax occurs when a subpleural bleb, most commonly in the lung apex, ruptures into the pleural space. In secondary spontaneous pneumothorax, rupture of the visceral pleura and alveolar barrier is most commonly due to the underlying pulmonary disease process.

Open Pneumothorax

Open chest wounds become symptomatic when the diameter of the chest wall defect approaches two thirds the size of the trachea. At this point, air preferentially enters the pleural cavity during inspiration (negative intrathoracic pressure) via the chest wall defect instead of the trachea, which leaves the lungs without oxygenation or ventilation.

Tension Pneumothorax

Tension pneumothorax occurs when a one-way valve develops in the injured lung and allows entry of air into the pleural space during inspiration without being able to escape during expiration. Tension physiology occurs when the increased intrathoracic pressure (15 to 20 mm Hg) limits the return of venous blood flow from the body to the right heart and compresses the great vessels and pericardium. Compression of the affected lung causes hypoxia and arterial constriction, which shunts blood flow mostly to the contralateral lung and decreases the magnitude of preload to the left atrium.

PRESENTING SIGNS AND SYMPTOMS

PNEUMOTHORAX

Classically, the symptoms of primary spontaneous pneumothorax are a sudden onset of ipsilateral, pleuritic chest pain and associated dyspnea. The pain typically begins at rest and is worsened with deep inspiration. It may eventually become a dull persistent ache that does not vary with respiration. Profound dyspnea is rare in the absence of tension pneumothorax or underlying parenchymal disease. Sinus tachycardia is the most common physical finding, with other classic signs such as decreased breath sounds, hyperresonance to percussion, unilateral enlargement of the hemithorax, absence of tactile fremitus, and decreased excursion volumes occurring less frequently. Symptoms may resolve in 24 hours without resolution of the pneumothorax. Many patients (45%) may delay seeking medical care for 48 hours. The severity of symptoms does not necessarily correlate with the size of the pneumothorax.

KEY POINTS

- Primary pneumothoraces (spontaneous or traumatic) occur in patients without clinically apparent lung disease.
- Chronic obstructive pulmonary disease is the most common cause of secondary pneumothorax.
- Physical examination may miss a pneumothorax occupying up to 27% of lung volume.
- Standard posteroanterior and lateral chest radiographs are the only routine examination needed because expiratory films add little to diagnostic accuracy.
- Ultrasound’s lung point sign has an overall sensitivity of 66% and a specificity of 100%.
- Treatment of pneumothorax is based on its cause, size and stability, symptoms, and the presence or absence of underlying lung disease. Treatment options include observation, catheter aspiration, and tube thoracostomy.

EPIDEMIOLOGY

Primary spontaneous pneumothorax occurs at a rate of 10 to 18 cases per 100,000 population per year in men and 5 cases per 100,000 in women. It has a peak incidence in young adults (20 to 30 years).

Secondary pneumothoraces make up one third of spontaneous pneumothoraces and occur with underlying pulmonary disease. Of note, chronic obstructive pulmonary disease (COPD) is the most common cause of secondary spontaneous pneumothorax. Recurrences are common, so prevention of recurrence is indicated after the first episode.

Patients with a spontaneous pneumothorax have a 30% recurrence rate within 2 years after air evacuation only; patients who have experienced two pneumothoraces have about an 80% chance of a recurrent pneumothorax.

PATHOPHYSIOLOGY

PNEUMOTHORAX

The pleural space lies between the parietal and visceral pleura and is normally negatively pressured at −5 mm Hg with fluctuations of 6 to 8 mm Hg between inspiration and expiration.
The ability of auscultation to detect hemothorax, pneumothorax, or hemopneumothorax associated with penetrating trauma had a sensitivity of 58%, a specificity of 98%, and a positive predictive value of 98% in one study. Auscultation can miss up to 600 mL of hemothorax, a pneumothorax occupying up to 28% of lung volume, and a combined hemopneumothorax of up to 800 mL and 28%. Physical examination alone is not sensitive enough to exclude the diagnosis of pneumothorax.

**OPEN PNEUMOTHORAX**
Patients with an open pneumothorax have significant dyspnea and a history of a penetrating wound to the thorax. Physical examination will reveal a chest wound that produces an audible, sucking air movement sound on inspiration and may bubble on expiration. Findings of a pneumothorax will also be present.

**TENSION PNEUMOTHORAX**
Patients with tension pneumothorax exhibit extreme dyspnea, hypotension, and cyanosis. Physical findings are hyperresonance, hyperinflation, absence of breath sounds on the affected side, and deviation of the trachea (at the sternal notch) away from the affected side. Tachycardia is often present and is defined as a pulse greater than 120 beats/min. Patients with tachycardia should undergo immediate tube thoracostomy (or needle thoracostomy if a chest tube is not immediately available) without waiting for a confirmatory radiograph.

**SECONDARY PNEUMOTHORACES**
Patients with pneumothoraces secondary to underlying lung disease may experience extreme dyspnea as a result of deflation of one lung and limited capacity and function of the remaining lung. Classically, symptoms do not resolve without intervention. Because of the underlying lung disease (most commonly COPD), lung findings may be abnormal, with hyperinflation and decreased lung sounds being noted.

### DIAGNOSTIC TESTING AND MEDICAL DECISION MAKING (TABLE 51.1)

#### RADIOGRAPHY
The primary evaluation tool is the standard posteroanterior chest radiograph to look for loss of lung markings in the periphery and a pleural line that runs parallel to the chest wall but does not extend outside the chest cavity. A lateral radiograph contributes to the diagnosis in 14% of cases. There is no evidence that an expiratory radiograph adds any value even with small apical pneumothoraces. The sensitivity for flat anteroposterior chest radiography, versus computed tomography (CT) as the “gold standard,” has been found to be 75.5%

<table>
<thead>
<tr>
<th>Table 51.1 Differential Diagnosis of Pneumothorax</th>
</tr>
</thead>
</table>
| Pulmonary embolism | Perform a risk stratification based on the Wells or Charlotte criteria.  
If the result of stratification is not low probability or the d-dimer test result is positive, proceed to computed tomography–pulmonary angiography.  
A chest radiograph may show infarcted lung. |
| Pleurisy | Look for an underlying disease process (connective tissue, pneumonia). Pleura-based diseases (pneumonia, tumor, effusion) often have radiographic findings. |
| Pneumonia | Chest radiography will be helpful. Clinical examination and the history may suggest pneumonia because of cough (uncommon with pneumothorax), upper respiratory symptoms, fever, or immunosuppression. |
| Pericarditis | Look for an underlying disease process. Check the electrocardiogram (ECG) for classic but not common PR-segment depression and/or widespread ST-segment elevation. Does position affect the pain (less with leaning forward, more with lying back)? Consider ultrasonography to diagnose effusion. |
| Myocardial infarction | Assess for appropriate risk factors. Evaluate with an ECG and cardiac marker measurements if suspicious. ECG findings associated with a pneumothorax include axis deviation, decreased voltage, and T-wave inversion. |
| Aortic dissection | Interscapular back pain with a tearing sensation is typical. Check the chest radiograph for a widened mediastinum, apical capping, left-sided pleural effusion, blurring of the aortic knob, or displacement of the trachea or esophagus to the anatomic right. Consider checking bilateral arm pressures. Look for a neurologic deficit or end-organ ischemia. |
| Musculoskeletal pain | Is the pain reproducible with palpation and use of the muscle group? Does the patient have a history consistent with muscle injury? Are the findings on chest radiography and ECG normal? |
| Pneumomediastinum | Is subcutaneous emphysema present on physical examination? Is mediastinal, pericardial, or prevertebral air found on the chest radiograph? Does it typically occur during a Valsalva maneuver or exertion? |
(95% confidence interval [CI], 61.7% to 86.2%), and the specificity is 100% (95% CI, 97.1% to 100%).

Shift of the mediastinum away from a pneumothorax on a chest radiograph can be a normal phenomenon that occurs without tension physiology. In critically ill patients in whom a radiograph can be taken only in the supine position, the emergency physician (EP) should look for the presence of a deep sulcus sign—a deep lateral costophrenic angle on the ipsilateral side (Fig. 51.1). Diaphragmatic depression or ipsilateral transradiancy (fewer lung markings, clearer image) may also be seen. Large bullae can be mistaken for a pneumothorax. With a pneumothorax, the pleural line runs parallel to the chest wall, whereas bullae more commonly have a medially concave appearance and are limited to a single lobe. A chest CT scan can help differentiate these entities. Pleural adhesions may alter the appearance of the pneumothorax by tethering the lung to the chest wall. Clothing, hair, and skin folds may appear as visceral pleural lines but often continue beyond the chest wall.

In most cases, an upright radiograph is sufficient to identify a pneumothorax. If not, EPs should consider additional modalities if they strongly suspect a pneumothorax, particularly if the patient is unstable, if underlying lung disease is present (and thus no reserve if a pneumothorax is missed), or if the patient is being treated with positive pressure ventilation.

ULTRASONOGRAPHY
Normal lung shows a shimmering echogenic stripe of both the parietal and visceral pleura on ultrasonography. A sliding sign at the pleural stripe can be seen with movement of the visceral pleura in relation to the parietal pleura. The “seashore analogy” refers to movement of the lung (ocean) against the stationary chest wall (shore). A comet tail reverberation can be seen distal to the pleura when no pneumothorax is present. The sliding sign of the pleural stripe and the comet tail reverberation are lost with a pneumothorax because of intrapleural air (Fig. 51.2). Doppler mode may be of some help in detecting this movement. Multiple other reasons can account for loss of the sliding, including atelectasis, mainstem intubation, acute respiratory distress syndrome, pleural adhesions, and pulmonary contusion, thus limiting specificity for pneumothorax in some cases.

Deep to this pleural line, vertical artifacts called B lines may be seen. They originate at the pleural line, align vertically, continue the entire depth of the screen without any fading, and move with breathing. The finding of B lines rules out the presence of a pneumothorax, but the absence of B lines does not signify the presence of a pneumothorax.

The lung point sign has a specificity approaching 100% for pneumothorax and is determined by the absence of lung sliding and B lines. The probe is moved gradually toward the lateral lower aspect of the chest. The goal is to identify lung sliding and B lines suggesting the “point” at which the lung is adherent to the pleura again (Fig. 51.3). A large pneumothorax may not display this point, thus diminishing the sensitivity of the lung point sign.

The sensitivity of ultrasound detection of pneumothorax has been found to be 98.1% (95% CI, 89.9% to 99.9%) and
the specificity was 99.2% (95% CI, 95.6% to 99.9%), which makes it more sensitive than a flat-plate anteroposterior radiograph.\textsuperscript{4} The use of ultrasonography as part of the extended focused assessment with sonography for trauma (eFAST) examination has been suggested in unstable patients with suspected pneumothorax.

**DOCUMENTATION**

Document the presence of underlying lung disease to establish the primary versus secondary status of the pneumothorax.

In the case of primary pneumothorax, document whether it was traumatic.

Document the estimated size of the pneumothorax and method of intervention.

If the patient is being discharged, document follow-up and discussion of reasons to return.

**COMPUTED TOMOGRAPHY**

CT is more accurate than radiography for the detection of pneumothoraces; it detects between 25% and 40% of pneumothoraces after lung biopsy that were not visualized on postprocedure chest radiographs.\textsuperscript{9} Up to 50% of traumatic pneumothoraces may be occult. CT can detect other problems, such as pulmonary blebs, vascular abnormalities, contusions, infiltrates, and tumors. CT is recommended in uncertain or complex cases such as symptomatic high-risk patients with suspected occult pneumothorax, those who have underlying lung disease, patients undergoing positive pressure ventilation, or those just completing lung biopsy.

**DETERMINING THE SIZE OF THE PNEUMOTHORAX**

Foremost, the degree of clinical symptoms is more important than the size of the pneumothorax in determining the appropriate therapy. Chest radiography underestimates the size of pneumothoraces because it is a two-dimensional view of a three-dimensional abnormality.

U.S. guidelines suggest measurement from the apex of the lung to the cupula of the thoracic cavity on an upright posteroanterior radiograph (Fig. 51.4). Less than 3 cm is considered small. British guidelines (2010) suggest the interpleural distance at the level of the hilum (Fig. 51.5). A 2-cm distance correlates with an approximate 50% pneumothorax by volume.\textsuperscript{10}

CT-directed size classification allows grading of occult pneumothoraces. Minuscule refers to air collections less than 1 cm thick that appear on fewer than five contiguous 10-mm slices. Anterior pneumothoraces are air collections more than 1 cm thick that appear on five or more contiguous 10-mm slices and do not extend to the midcoronal line (Fig. 51.6). Anterolateral pneumothoraces extend to the midcoronal line or beyond.

**TREATMENT**

**PRIORITY ACTIONS**

1. Administer oxygen.
2. Determine whether tension pneumothorax physiology exists. If present, proceed to tube thoracostomy without delay for imaging.
3. Close an open pneumothorax with a three-sided dressing.
4. Obtain posteroanterior and lateral chest radiographs.
5. Determine the size of the pneumothorax.
6. Assess the patient for underlying lung disease, adhesions, and other complications.
PREHOSPITAL MANAGEMENT

**Tension Pneumothorax**

Emergency needle aspiration is usually performed by emergency medical services personnel when tension pneumothorax is suspected. In an ED setting, placement of a chest tube more reliably and more definitively addresses the problem in a relatively short time.

**Open Pneumothorax**

An open pneumothorax should be taped on three sides with material that will be airtight. An airtight seal can be accomplished with petrolatum gauze (Xeroform) or the aluminum foil of the gauze packaging. Securing only three sides prevents the development of tension pneumothorax by allowing escape of air from the pleural space via this one-way valve.

HOSPITAL MANAGEMENT

Oxygen should be administered to all patients with a pneumothorax because it helps in resorption of the pneumothorax and increases oxygenation of the available alveoli in the noncollapsed lung. The untreated resorption rate is 1% to 2% per day, and the rate increases fourfold with the administration of 100% oxygen.

The stability of the patient, the severity of the symptoms, the current size of the pneumothorax, the change in size over time, the cause of the pneumothorax (primary, secondary, traumatic), and the severity of the underlying lung disease must all be considered in the decision whether to intervene in a patient with pneumothorax.

A stable patient with pneumothorax has been described as one who has a respiratory rate of less than 24 breaths/min, a heart rate between 60 and 120 beats/min, normal blood pressure, oxygen saturation greater than 90% when breathing room air, and the ability to speak in full sentences between breaths.

Figures 51.7 and 51.8 present algorithms to assess the need for intervention in patients with primary spontaneous pneumothorax or traumatic pneumothorax, respectively.

Patients with bilateral pneumothoraces are treated by aspiration or chest tube placement.

Patients with secondary pneumothoraces should be admitted to the hospital. A patient who is not at risk for large air leaks and has a small pneumothorax can be treated by aspiration via a small-bore catheter. A clinically unstable patient or a stable patient with a large pneumothorax should be treated with a chest tube.

Chest tube sizes for patients with spontaneous pneumothoraces are recommended as follows. Catheter (simple) aspiration seems to be as effective as chest tube treatment in patients with a small pneumothorax. Aspiration of more than 2.5 L of air suggests an air leak and may require a small-bore chest tube. Clinically stable patients with a large pneumothorax are treated by aspiration via a small-bore catheter (14 to 16 gauge) or with a 14 French (14F) chest tube. Clinically unstable patients with a large primary pneumothorax should be treated by tube thoracostomy. A larger (14F to 28F) chest tube should be used for patients requiring positive pressure ventilation and those at risk for large pleural air leaks (bronchopleural fistula). With traumatic pneumothoraces, a 28F to 36F chest tube should be used because of the risk for associated hemothorax.

Postprocedure monitoring and radiographs should be obtained to assess the success of the intervention and the position of the chest tube.

**Heimlich Valve**

A Heimlich valve is a one-way valve that can be attached to the end of a chest tube. Suction has not been proved to aid in reexpansion or the outcome of a pneumothorax, and it is not recommended. Instead, a water seal or Heimlich valve is used. A Heimlich valve allows the patient to ambulate unrestricted. It should not be used in patients with underlying lung disease or other medical problems that prevent them from tolerating a recurrence of the pneumothorax. Complications of this method include obstruction of the valve with fluid and disconnection.
Consultation

Decisions regarding catheter aspiration versus chest tube treatment for a pneumothorax should include the input of the physician who will continue care, either in the hospital or on an outpatient basis.

Any patient with a persistent air leak after tube thoracostomy, a history or findings of pleural adhesions, recurrent pneumothoraces, or secondary pneumothoraces should be discussed with the chest surgeon to determine optimal care. Such care may include video-assisted thoracic surgery or pleurodesis.

Follow-up, Next Steps in Care, and Patient Education

Disposition

The disposition of patients with pneumothorax is detailed in the algorithms in Figures 51.7 and 51.8. A patient with a primary spontaneous pneumothorax who has been treated by observation or catheter aspiration can be discharged if the pneumothorax does not increase over a period of 3 to 6 hours and the symptoms do not worsen. For a patient discharged with a primary spontaneous pneumothorax without intervention, follow-up should occur in the next 24 to 48 hours to document stability or resolution of the pneumothorax.

In patients with a secondary (associated with underlying lung disease) spontaneous pneumothorax, the treatment algorithm is altered by the underlying lung disease. Clinically stable patients, regardless of the duration of symptoms, should not be monitored in the ED or treated with catheter aspiration and discharged. They should all be admitted to the hospital for observation, simple aspiration, or tube thoracostomy.\(^\text{13}\)

Complications

Complications of pneumothorax include those related to hypoxia, hypercapnia, and hypotension. Reexpansion lung injury is rare but most commonly occurs after reexpansion of
**CHAPTER 51  PNEUMOTHORAX**

**PATIENT TEACHING TIPS**

- The patient must stop smoking.
- There is no limitation on physical activity.
- Patients should return to the emergency department immediately for recurrence of symptoms.
- Safety regulations state that a patient cannot fly for 3 weeks after treatment, and diving is also contraindicated.
- A patient with a primary spontaneous pneumothorax has a 30% recurrence rate within 2 years after air evacuation only; a patient who has had two pneumothoraces has an 80% chance of recurrence.
- Patients sent home after observation should undergo follow-up within 24 to 48 hours to document stability or resolution of the pneumothorax.

**RED FLAGS**

- Intercostal vessel hemorrhage
- Lung parenchymal injury
- Tube malfunction
- Air leak
- Development of tension pneumothorax
- Reinflation pulmonary injury
- Infection of the wound site
- Entry into the wrong body cavity
- Subcutaneous tube insertion

---

**Fig. 51.8** Algorithmic approach to the treatment of traumatic pneumothorax. CT, Computed tomography; PTX, pneumothorax.
a large pneumothorax. Risk factors appear to include collapse of the lung for longer than 72 hours, a large pneumothorax, rapid reexpansion, and use of negative pleural pressure suction greater than 20 cm H$_2$O.$^{14}$

Persistent air leaks occur when the volume of air escaping into the pleural space is greater than the volume of air being removed by the drainage device. This complication is more common with a pneumothorax secondary to underlying lung disease. Typically, such air leaks resolve spontaneously within a week (in 75% of patients with a primary pneumothorax and in 61% with a secondary pneumothorax). If an air leak persists beyond 7 days, surgical intervention should be considered.

Complications that can occur during chest tube placement or catheter aspiration include intercostal vessel damage and hemorrhage, lung parenchymal injury, and tube malfunction.

Pleural Effusion

Bret A. Nicks and David E. Manthey

Nature) can usually be explained by either increased pleural fluid formation or decreased pleural fluid absorption, or both. Pleural effusions caused by an increase in pleural fluid formation can be further subdivided into elevation in hydrostatic pressure (e.g., congestive heart failure), decreased colloid osmotic pressure (e.g., cirrhosis, nephrotic syndrome), increased capillary permeability (e.g., infection, neoplasm), passage of fluid through openings in the diaphragm (e.g., ascites), or reduction of pleural space pressure (e.g., atelectasis). An effusion caused by decreased pleural fluid absorption can be qualified further as either lymphatic obstruction or elevation of systemic venous pressure resulting in impaired lymphatic drainage (e.g., superior vena cava syndrome).

The presence of fluid in the normally negative pressure environment of the pleural space has a number of consequences for respiratory physiology. Pleural effusions produce a restrictive ventilatory defect and also decrease total lung capacity, functional residual capacity, and forced vital capacity. They may cause ventilation-perfusion mismatches and, when large enough, compromise cardiac output.\(^2\)

The classic work of Light et al.\(^3\) in 1972 demonstrated that 99% of pleural effusions could be classified into these two general categories, transudative and exudative (Box 52.1). A basic difference is that transudates generally reflect a systemic process whereas exudates usually signify underlying local pleuropulmonary disease.\(^3\)

**PRESENTING SIGNS AND SYMPTOMS**

In many cases, pleural effusions are asymptomatic when discovered. Physical findings of pleural effusions are unlikely to be manifested until an effusion exceeds 300 mL. Dyspnea, the most common symptom associated with pleural effusion, is related more to distortion of the diaphragm and chest wall during respiration than to hypoxemia. Less commonly, symptoms of pleural effusions consist of a mild, nonproductive cough and chest pain. Pleuritic chest pain indicates inflammation of the parietal pleura because the visceral pleura is not innervated. In many patients, drainage of pleural fluid alleviates the symptoms despite limited improvement in gas exchange. Findings on lung examination such as decreased breath sounds, dullness to percussion, pleural friction rub, egophony, and reduced tactile fremitus have all been described.\(^4,5\) Auscultation alone can miss up to 600 mL of fluid in the lung.\(^4,6\)

**KEY POINTS**

- Pleural effusion is the manifestation of an underlying disease process.
- The most common cause of pleural effusion in developed countries is congestive heart failure.
- Pulmonary embolism should be considered in patients with pulmonary effusions of uncertain etiology.
- Therapeutic thoracentesis is indicated in the emergency department for relief of acute respiratory or cardiovascular distress.
- Diagnostic thoracentesis should be performed in the emergency department to diagnose immediately life-threatening conditions in toxic-appearing patients.
In 1972, Light et al. developed the currently accepted benchmark for classifying pleural fluid, as follows:
- Pleural fluid protein-to-serum protein ratio > 0.5:1
- Pleural fluid lactate dehydrogenase (LDH)-to-serum LDH ratio > 0.6:1
- Pleural fluid LDH greater than two thirds the upper limit of normal for serum LDH (a cutoff value of 200 IU/L was used previously)

Pleural fluid is classified as an exudate if it meets any of the aforementioned criteria. Conversely, if all three characteristics are absent, the fluid is classified as a transudate. These researchers achieved a diagnostic sensitivity of 99% and specificity of 98% for classification of an exudate.

**Box 52.2 Signs and Symptoms of Effusion**

Dyspnea  
Cough (dry, nonproductive)  
Chest pain (pleuritic or nonpleuritic)  
Chest wall discomfort  
Decreased breath sounds  
Dullness to percussion  
Egophony, tactile fremitus  
Pleural friction rub  
Disease-specific signs and symptoms may include:  
Orthopnea  
Paroxysmal nocturnal dyspnea  
Fever  
Night sweats

*A detailed past medical history may uncover the cause of the effusion.*

The emergency physician should assess for the cause of the effusion. If a patient complains of fever, weight loss, and a progressively worsening cough with associated dyspnea, an oncologic or infectious cause is likely. Constant chest wall pain may reflect chest wall invasion by bronchogenic carcinoma or malignant mesothelioma. Pleuritic chest pain suggests either pulmonary embolism or an inflammatory pleural process. An effusion can mimic the classic symptoms of acute coronary syndrome, such as chest pain, dyspnea, and shoulder pain (Box 52.2).

The causes of pleural effusion are broad and include:

**Transudates**  
Atelectasis (early)  
Congestive heart failure  
Cirrhosis  
Glomerulonephritis  
Hypoalbuminemia  
Myxedema  
Nephrotic syndrome  
Peritoneal dialysis  
Pulmonary embolism  
Superior vena cava syndrome

**Exudates**  
**Infectious**  
Bacterial infection  
Bronchiectasis  
Fungal infection  
Lung abscess  
Parasitic infection  
Traumatic hemothorax  
Tuberculosis  
Viral illness

**Malignancies**  
Lymphoma  
Mesothelioma  
Primary lung cancer  
Pulmonary metastasis

**Connective Tissue Disease**  
Rheumatoid arthritis  
Systemic lupus erythematosus

**Abdominal/Gastrointestinal**  
Esophageal rupture  
Pancreatic disorders  
Subphrenic abscess

**Other**  
Atelectasis (chronic)  
Chylothorax  
Drug reactions (amiodarone)  
Postpartum state  
Pulmonary infarction or embolism  
Uremia

A pleural effusion is frequently identified during evaluation of the underlying chief complaint of the patient. Because the etiology of pleural effusion is myriad, a thorough history and physical examination may narrow the differential diagnosis substantially. Box 52.3 lists the common causes of pleural effusion. Frequently, effusion is identified on physical examination or with basic chest radiography, but additional imaging modalities, including radiography, ultrasonography, and computed tomography (CT), may identify the cause and provide additional insight about the effusion.

**Box 52.3 Causes of Pleural Effusions**

**Transudates**
- Atelectasis (early)
- Congestive heart failure

  - Systemic lupus erythematosus

- **Abdominal/Gastrointestinal**
  - Esophageal rupture
  - Pancreatic disorders
  - Subphrenic abscess

- **Other**
  - Atelectasis (chronic)
  - Chylothorax
  - Drug reactions (amiodarone)
  - Postpartum state
  - Pulmonary infarction or embolism
  - Uremia

**Differential Diagnosis and Medical Decision Making**

Auscultation alone can miss effusions of up to 600 mL. Effusions of approximately 400 mL are routinely visible on upright chest radiographs. Bedside ultrasonography is effective for visualizing and characterizing effusions. Ultrasound-guided thoracentesis should be performed when available.
DIAGNOSTIC CONSIDERATIONS

RADIOGRAPHY
Erect posteroanterior and lateral chest radiographs are still the most important initial tools in the diagnosis of a pleural effusion. On upright and lateral decubitus films, loss of the costophrenic angle is seen. With increasing size of the pleural effusion, the hemidiaphragm is obscured (Fig. 52.1), and a mass effect with shift of the mediastinum away from the affected side is noted. If a film is taken with the patient supine, one may see only a nonspecific haze over the affected hemithorax because the fluid layers posteriorly. To confirm that the fluid is free flowing, lateral decubitus films with the affected side down are often obtained. With very large effusions, the affected side may remain opacified, thus rendering the decubitus film unhelpful. In adults the minimum amount of fluid required for identification of effusion on an upright film is approximately 400 mL, whereas lateral decubitus films (with the affected side down) may detect as little as 50 mL of fluid. A lateral decubitus film with the affected side up may facilitate evaluation of the underlying lung for atelectasis, a mass, or infiltrates along the lateral portion of the lung.5,6

Mediastinal shift contralateral to the effusion (observed with effusions > 1000 mL) with concomitant displacement of the trachea is an important clue to obstruction of a lobar bronchus by an endobronchial lesion, possibly because of malignancy or, less commonly, obstruction by a foreign body.

Subpulmonic effusions are an uncommon manifestation of pleural effusions seen when fluid accumulates between the lower lung lobe and diaphragm. The fluid collection may mimic an elevated hemidiaphragm in upright imaging (Fig. 52.2). Upward of 400 mL of fluid can collect in the subpulmonic region before the posterior costophrenic sinus is filled. Evidence of an elevated hemidiaphragm with steep lateral peaks, obscured pulmonary vessels below the level of the diaphragm on a lateral projection, or a flat appearance of the posterior aspect of the hemidiaphragm on a lateral projection is suggestive of a subpulmonic effusion.6

ULTRASONOGRAPHY
Ultrasoundography is effective for visualizing an effusion and determining whether the fluid is free flowing or loculated (Fig. 52.3).7-9 In a prospective study, Piccoli et al.8 compared ultrasonography, physical examination, and radiography in patients with suspected effusions. Findings on physical examination and radiography were in agreement 76% of the time, with a kappa value of 0.52. When compared with chest ultrasoundography, physical examination showed a sensitivity of 69% and a specificity of 77%. Ultrasonography may help distinguish a large solid chest mass from an effusion and can be used to guide thoracentesis. Ramnath et al.10 suggested early use of ultrasonography to identify complicated effusions (loculations or organization) because patients whose effusions were

Fig. 52.1 Large parapneumonic effusion on an upright chest radiograph.

Fig. 52.2 A subpulmonic effusion may mimic the surface of the diaphragm without blunting the costophrenic angle.

Fig. 52.3 Upright bedside ultrasonogram of a large pleural effusion.
treated aggressively by decortication had significantly shorter hospital stays than did those whose effusions were treated with tube thoracostomy alone. The same study showed that in children with effusions but no ultrasonographic evidence of organization, outcomes in those receiving treatment consisting of intravenous antibiotics and drainage were similar to outcomes in those undergoing aggressive treatment such as thoracotomy or decortication. The major advantage of ultrasonography over conventional radiography is its ability to differentiate between solid and liquid components, thereby assisting in identification of pleural fluid loculations.

**COMPUTED TOMOGRAPHY**

CT is rarely needed to diagnose a pleural effusion but may identify an underlying mass. In adults the presence of parietal pleural thickening on contrast-enhanced CT is a specific but insensitive indicator of an exudate. Cross-sectional imaging more clearly distinguishes anatomic compartments such as the pleural space from lung parenchyma (Fig. 52.4). Chest CT is likely to be valuable in making management decisions for complicated effusions because it can distinguish empyema from lung abscess, detect pleural masses, outline loculated fluid collections, and identify additional problems such as contusions, blebs, and infiltrates.

**PLEURAL FLUID ANALYSIS**

Ideally, evaluation of a pleural effusion should begin with diagnostic thoracentesis and proceed to classification of the pleural fluid as either a transudate or an exudate. The currently accepted benchmark for classifying pleural fluid, developed by Light et al.,\(^1\) is shown in Box 52.1. A number of later studies used modifications of the Light criteria but had poorer diagnostic accuracy.\(^3\)

Normal pleural fluid pH has been estimated to be approximately 7.64. A pH below 7.30 suggests the presence of an inflammatory or infiltrative process, such as parapneumonic effusion, empyema, malignancy, connective tissue disease, tuberculosis, or esophageal rupture. According to the current American College of Chest Physicians consensus statement on the treatment of parapneumonic effusions, pH is the preferred pleural fluid chemistry test for classifying the category of a parapneumonic effusion for subsequent management (Box 52.4).\(^{13,14}\) Additional testing considerations for pleural fluid include cholesterol, glucose, amylase, and adenosine deaminase.\(^{11,13,14}\)

**RED FLAGS**

- Failure to establish a working differential diagnosis or identify the underlying cause
- Failure to initiate prompt source management for an underlying infectious cause
- Failure to identify and manage tension physiology caused by large effusions on an emergency basis

**TREATMENT**

Acute medical management of pleural effusions is based on both therapeutic and diagnostic considerations. In the emergency department (ED), therapeutic thoracentesis is indicated for relief of acute respiratory or cardiovascular distress. Diagnostic thoracentesis should be used in the ED to diagnose immediately life-threatening conditions in toxic-looking patients. Circumstances outside these situations should not necessitate emergency thoracentesis, but appropriate monitoring and further medical management are essential. Table 52.1 summarizes findings dictating the appropriateness of intervention.\(^13\)

**APPROACH TO UNILATERAL PLEURAL EFFUSION**

Thoracentesis should be performed for new and unexplained pleural effusions when sufficient fluid is present to allow a safe procedure. Conventional wisdom holds that if a 10-mm layer of fluid is visible on a radiograph, sufficient fluid is present for thoracentesis to be successful. Treatment of the underlying disorder is generally all that is required for effusions caused by renal, cardiac, or rheumatologic diseases.
Thoracentesis is an elective procedure requiring informed consent. Sterile technique and procedural experience lower the incidence of complications. Drainage of a pleural effusion is indicated for the following reasons:

- Diagnostic fluid or cellular analysis
- Therapeutic relief of symptomatic dyspnea
- Evaluation of complicated parapneumonic effusions or empyema

**POSITIONING**

Ideally for thoracentesis, the patient should sit on the edge of the bed, lean forward slightly, and rest on an adjustable table. If the patient cannot sit up because of hemodynamic status, mental status, or the presence of tubes and indwelling lines, thoracentesis can be performed with the patient supine. In this case, the patient should turn onto the side with the effusion and move to position the back at the edge of the bed.

**PROCEDURAL APPROACH**

Diagnostic thoracentesis is used to determine the cause of a pleural effusion, and therapeutic thoracentesis is performed to relieve symptoms of respiratory distress. Therapeutic thoracentesis may be repeated if indicated, but more definitive therapy such as sclerosis is usually needed to treat recurrent symptomatic pleural effusions. If more than 1.0 to 1.5 L of fluid is removed at one time, reexpansion pulmonary edema (RPE) and postthoracentesis shock should be anticipated in the postprocedural period. Supplemental oxygen should be provided because postthoracentesis decreases in arterial oxygenation have been reported. The magnitude and duration of this decline roughly correlate with the amount of fluid removed. If removal of a large volume of fluid is anticipated, concurrent fluid resuscitation should be considered to blunt postthoracentesis shock. Depending on the causative process, reaccumulation of pleural fluid may occur.

After appropriate positioning, the patient is prepared in standard sterile fashion. The effusion can be identified along with the patient's history and examination. Thoracentesis is performed using a local anesthetic and a sterile technique. The pleural fluid is aspirated with a large-bore needle or catheter, and the patient is observed for any adverse effects.
the posterior infrascapular line by either clinical examination (auscultation and percussion) or bedside ultrasonography. Ultrasonography is recommended because it identifies not only the level of effusion but also the subdiaphragmatic organs that should be avoided and the depth of the fluid pocket. As the angiocatheter is advanced, the neurovascular bundles located on the inferior aspect of the ribs should be avoided. Aspiration of fluid can continue until enough fluid is obtained for diagnostic purposes or therapeutic relief.

Needle thoracentesis is adequate for both diagnostic evaluation and therapeutic management of most parapneumonic pleural effusions. When the effusion has progressed to the fibrinopurulent or organizational stage, needle thoracentesis is often inadequate. Thoracoscopy offers the advantages of visual evaluation of the pleura, direct tissue sampling, and therapeutic intervention such as dissecting loculations and pleurodesis. Appropriate consultation for medical thoracoscopy and video-assisted thoracoscopy is indicated in these circumstances.

### CONTRAINDICATIONS

Procedural contraindications to pleurocentesis or thoracotomy are listed in Box 52.5. Absolute contraindications include coagulopathy, known adhesions, and a history of pleurodesis. If the patient is symptomatic and coagulopathic, correction of coagulopathy and ultrasonographic guidance are recommended to minimize bleeding risks. Pleurodesis, or the introduction of a chemical or medication (talc, tetracycline, or bleomycin sulfate) into the chest cavity, triggers an inflammatory reaction over the surface of the lung and inside the chest cavity that causes the pleurae to adhere to each other and prevents or reduces further accumulation of pleural fluid. Thoracentesis should be avoided in patients at increased risk for adverse reactions as a result of unstable angina or arrhythmia or known medical noncompliance, including lack of established outpatient care. Relative contraindications include mechanical ventilation because of an increased risk for lung collapse and difficulty with positioning. In intubated patients, use of ultrasonography or CT for thoracentesis or postponing the procedure is recommended if the indication is not urgent. Patients with known bullous lung disease are at increased risk for postprocedural pneumothorax. Placement of the thoracentesis needle through a concurrent chest wall infection should be avoided because the pleural space may become seeded. A postprocedure radiograph should always be obtained to assess for pneumothorax.

### COMPLIICATIONS

Adverse outcomes associated with pleural effusions can be characterized as iatrogenic or pathologic. Thoracentesis can predispose patients to pneumothorax, acute RPE, shock, subsequent fluid reaccumulation, bleeding, infection, and solid organ injury. If untreated, the parapneumonic effusion can progress to fibrinopurulent empyema, which frequently requires surgical intervention.

If the patient complains of increasing respiratory distress within the first hour after thoracentesis, RPE or pneumothorax may be occurring, and an emergency chest radiograph should be obtained. RPE is a syndrome associated with hypotension and hypoxemia. It is thought to be a result of combined alveolar-capillary membrane disruption initiated by distention, reperfusion-mediated injury, and increased pulmonary flow. Risk factors include previous atelectasis and rapid reexpansion of the lung parenchyma. Typically, a patient with significant RPE becomes symptomatic within 15 minutes to 2 hours after rapid reexpansion of the lung. Treatment is based on adequate oxygenation and circulation, generally with positive end-expiratory pressure. Concern about the potential for RPE after thoracentesis is important because mortality in patients with this condition is consistently 15% to 20% despite mechanical ventilation.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

In many cases, small pleural effusions are identified during evaluation of the patient’s chief complaint. Although not all effusions require immediate drainage, when thoracentesis is performed, stable patients with a clear etiology and well-established care plan may be discharged after an appropriate observation period of 3 to 6 hours. Patients with large-volume evacuation or exudative effusions or those who require further evaluation and stabilization should be admitted to the hospital.

Close outpatient follow-up and management are required for all patients evaluated for pleural effusion, regardless of whether they underwent thoracentesis, to further address the underlying cause and monitor the effusion.
Pleural effusions represent an underlying disease process that must be addressed. Possible complications of pleural effusions include pneumothorax, respiratory failure secondary to massive fluid reaccumulation, septicemia, bronchopleural fistula, and pleural thickening. Follow-up is recommended for all patients undergoing thoracentesis. Some experts recommend serial chest radiographs to ensure clearing. Some perform computed tomography after plain radiographs show clearing.

Establish bedside ultrasonography as part of assessment for pleural effusions. Consider pulmonary embolism with an uncertain pleural effusion etiology. Ultrasound-guided thoracentesis enhances visualization and minimizes complications. Complicated pleural effusions may require surgical intervention. “Two-test” and “three-test” rules for pleural fluid analysis exist but are not as specific as the Light criteria.

53 Lung Transplant Complications
Michael K. Abraham and Robert L. Rogers

KEY POINTS

- All lung transplant recipients with respiratory complaints should be assessed for the possibility of rejection and parenchymal lung infection. In most cases, assessment leads to admission to the hospital.
- Rejection and pulmonary infection are frequently indistinguishable. The clinical manifestation of pneumonia and lung allograft rejection may be subtle, and admission is required to address both entities.
- Lung rejection is common and can occur anytime after transplantation.
- Transplanted lungs are highly susceptible to pneumonia. Cytomegalovirus pneumonia is the most common opportunistic pulmonary infection after lung transplantation.

SCOPE

A lung transplant recipient may seek care in the emergency department (ED) as a result of complications related to the surgical procedure, infections, or medication interactions. The main worry when dealing with transplant patients is to identify the threat for lung allograft rejection and begin treatment if necessary. To complicate matters, potent immunosuppressive regimens may mask serious or life-threatening infectious diseases in organ transplant recipients. This chapter provides information to arm the emergency physician (EP) with the knowledge necessary to take care of this complex group of patients.

More than 1500 lung transplants are performed each year in the United States; worldwide, approximately 3000 were performed in 2009. Survival rates had been rising in recent years because of technologic advances in surgical technique and immunobiology, but they seem to have reached a plateau. The current survival rate 1 year after transplantation is 79%. Multiple conditions necessitate lung transplantation, including cystic fibrosis, end-stage chronic obstructive lung disease, and interstitial lung disease (Box 53.1). The primary reason for bilateral lung transplantation is chronic obstructive pulmonary disease.

The number of patients who have undergone solid organ transplantation increases every year. In 2008 alone, 27,281 organ transplantations were performed in the United States. This figure represents a large number of patients who might seek medical care in an ED. In addition, current survival rates are rising. In 1998, 1-, 3-, and 5-year survival rates were 70.7%, 54.8%, and 42.6%, respectively, for lung transplant recipients. In 2009, the rates were 79%, 63%, and 52%. Although survival rates for lung transplantation lag behind those for other solid organ transplantations, enhancements in immunotherapy will probably continue to advance.

COMPlications Related to the Surgical Procedure

The type of transplant (single lung, double lung, combined heart and lung, lobar) depends on the recipient’s disease and the particular transplant center where the procedure is performed. Single-lung transplantation requires a lateral thoracotomy incision, and double-lung transplantation requires a double thoracotomy (“clamshell”) incision. The heart may be transplanted along with one or both lungs. In some cases, a lobar segment of donor lung is transplanted. The surgical procedure includes anastomosis of the pulmonary arteries, veins, and bronchus.

EMERGENCY DEPARTMENT PRESENTATION

Patients who have undergone lung transplantation should be considered high risk when seen in an ED for evaluation. Because many patients live far from the facility where their surgery was performed, they are likely to go the nearest ED when problems arise. In a retrospective review of 131 lung and heart-lung transplant patients who visited an ED, the most common complaints were fever (37%), shortness of breath (13%), gastrointestinal symptoms (10%), and chest pain (9%).

ED manifestations of lung transplant recipients are commonly related to complications of the surgical procedure and immunosuppression. Disease unrelated to the transplant may also be present.
Lung transplantation may require immediate therapy in some cases, the emergence of rejection necessitates retransplantation. The majority of transplant recipients experience at least one episode of rejection. Patients who experience repeated episodes of allograft rejection are at increased risk for chronic rejection (bronchiolitis obliterans syndrome).9-11

The clinical findings in patients with lung allograft rejection can be nonspecific or even silent12 (Box 53.2). Patients may report a dry cough, subjective fevers, varying degrees of shortness of breath, or any combination of these symptoms. Episodes of rejection cannot be distinguished from pulmonary infection on clinical grounds alone.9 The important point for EPs to remember is that the symptoms of allograft dysfunction or rejection may be subtle. Patients may not appear ill or seem to have anything more than a viral upper respiratory tract infection.13,14

During the first 6 months after transplantation, chest radiographs may show pleural effusions, interstitial edema, or peripheral infiltrates. Episodes of rejection occurring after this time tend to not lead to abnormalities on the chest radiograph. Normal chest film findings do not rule out the presence of underlying rejection. In the ED, chest radiographs may help in the evaluation of entities that would require immediate therapy, such as pneumothorax or a large pleural effusion.13,14

Infectious complications after organ transplantation have been studied extensively and are related to multiple factors, the most important being the time since transplantation. Infections in organ recipients can be broken down into three periods (Fig. 53.1).

During the first month after transplantation, nosocomial infections predominate. Wound infections, urinary tract infections, pneumonia, and vascular access infections are common in this period. Opportunistic infections, such as those caused by Pneumocystis and Nocardia species, do not usually occur in the first month after transplantation.22 Infections that emerge 1 to 6 months after solid organ transplantation include many of the opportunistic infections, such as those caused by Pneumocystis carinii and Listeria monocytogenes. In addition,
immunomodulating viruses (particularly cytomegalovirus [CMV]) become important pathogens. Epstein-Barr virus, hepatitis B virus, hepatitis C virus, and human immunodeficiency virus can also produce infection during this time frame.22

Viral infections that emerge after the first month following transplantation may be associated with chronic or progressive infection and may cause significant injury to the affected transplanted organ. Patients who experience chronic or recurrent bouts of organ rejection are invariably exposed to higher and prolonged periods of immunosuppressive therapy and thus tend to be vulnerable to these opportunistic pathogens.1

PULMONARY INFECTIONS
The lungs are particularly vulnerable to infection after solid organ transplantation. The highest risk for posttransplantation pulmonary infection occurs in lung transplant recipients. Pulmonary infections are the most common infectious complication in heart and lung transplant recipients19-21 and the least common in kidney transplant recipients.21 Multiple factors explain this higher incidence of lung infections (Box 53.3).

Organisms that commonly cause pulmonary infection in the postoperative period are gram-negative organisms (nosocomial) and Staphylococcus aureus. Community-acquired bacterial pneumonia tends to occur later in the posttransplantation period.19 Causative organisms include Haemophilus influenzae, Streptococcus pneumoniae, and Legionella species. Most cases of bronchiolitis obliterans syndrome are caused by Pseudomonas aeruginosa. Patients with this syndrome commonly have recurrent episodes of purulent bronchitis and pneumonia.21 Other infections to consider are fungal pneumonia and tuberculosis (Table 53.1).

Pulmonary infections in transplant patients may not cause the symptoms seen in other outpatients who have not received a transplant. As stated earlier, the symptoms may be subtle and may be as simple as a dry cough and mild upper respiratory tract discomfort. Fever in a patient receiving immunosuppressive treatment is a worrisome sign and may be the only manifestation of a serious underlying lung infection such as pneumonia. Many lung transplant recipients do not look that ill initially or do not have fulminant symptoms of pneumonia when first evaluated (Fig. 53.2).
When a lung transplant recipient is being evaluated in an ED, pulmonary infection must be highest on the differential diagnosis, and the patient’s pulmonary or transplant physician should be contacted. Any suspicion of a pulmonary infection warrants the administration of broad-spectrum antibiotics that cover common community-acquired pathogens and health care–associated pathogens, including *Pseudomonas* species. In most cases, patients in whom pulmonary infection is suspected are admitted to the hospital or transferred to another facility where they will probably undergo fiberoptic bronchoscopy.

*Acute illness* develops and requires medical attention in less than 24 hours. *Subacute or chronic illness* develops over a period of several days to a week.

†A nodular infiltrate is one or more focal defects greater than 1 cm² in area on chest radiographs with well-defined borders and surrounded by aerated lung. Multiple tiny nodules are seen in a wide variety of disorders (e.g., cytomegalovirus, varicella-zoster virus infection) and are not included here.

**Fig. 53.2** Computed tomography (CT) scan of the chest showing an atypical infection. This is a CT scan of the chest with intravenous contrast enhancement in a bilateral lung transplant recipient. The patient came to the ED with a complaint of shortness of breath. The patient’s plain chest radiograph was interpreted as normal. The CT scan was negative for pulmonary embolism but shows diffuse inflammation. Bronchoscopy performed as an inpatient procedure was positive for *Pseudomonas aeruginosa* infection.
lung transplant recipients after bacterial pneumonia. The are asymptomatic initially. A prodrome consisting of fever, malaise, and myalgias frequently precedes the onset of pneumonitis (cough and dyspnea). The disease may appear as opacities, nodules, or lobar infiltrates on chest radiographs.29,30

Further inpatient work-up (i.e., bronchoscopy) is generally required to distinguish the cause. CMV pneumonitis is diagnosed through serologic testing and the results of bronchoscopy, discussion of which is beyond the scope of this chapter. As many as 10% to 15% of patients with CMV pneumonitis are asymptomatic initially. A prodrome consisting of fever, malaise, and myalgias frequently precedes the onset of pneumonitis (cough and dyspnea). The disease may appear as opacities, nodules, or lobar infiltrates on chest radiographs.29,30

Treatment of CMV infection may start in the ED. The diagnosis of CMV infection may not be established on initial evaluation, but a presumptive diagnosis is frequently made and empiric therapy started. Standard treatment of CMV infection consists of a 2- to 3-week course of intravenous ganciclovir.31 In some cases, ganciclovir is combined with CMV hyperimmune globulin. These therapies are usually started after the patient has been admitted.31

All lung transplant recipients seen in an ED within the vulnerable period of 1 to 3 months after surgery should be evaluated carefully for CMV disease. It should be assumed that any lung transplant recipient who underwent transplantation less than 3 months previously and who has fever, cough, or other suspicious findings may have active CMV disease. In many cases, therapy is started in the ED in consultation with the patient’s physician.

**CYTOMEGALOVIRUS INFECTION**

CMV causes one of the most important and lethal infections in solid organ recipients.23 This virus, referred to as the “troll of transplantation,” is the second most common infection in lung transplant recipients after bacterial pneumonia.24 The overall likelihood of CMV infection in a lung transplant recipient is approximately 50% and is related to the CMV status of the donor and recipient.25

CMV infection generally occurs 1 to 3 months after transplantation. Any episode of acute rejection raises the patient’s risk for continued CMV infection because of the immunosuppression required. The clinical findings may range from asymptomatic viremia to overwhelming sepsis and multiorgan failure. True clinical disease may be manifested as a mononucleosis-like syndrome with fever, malaise, and leukopenia (Box 53.4). There may also be organ-specific involvement in the lungs (pneumonitis), gastrointestinal system (colitis and hepatitis), and central nervous system. Over time, CMV infection leads to a high level of immunosuppression and the subsequent development of chronic allograft dysfunction and possibly failure.23,26,27

Pneumonitis is the most common manifestation of CMV disease after lung transplantation.29 Clinically, CMV pneumonitis may look like acute rejection. Patients with either acute lung allograft rejection or CMV pneumonitis may have low-grade fever, a nonproductive cough, and shortness of breath. Further inpatient work-up (i.e., bronchoscopy) is generally required to distinguish the cause. CMV pneumonitis is diagnosed through serologic testing and the results of bronchoscopy, discussion of which is beyond the scope of this chapter. As many as 10% to 15% of patients with CMV pneumonitis are asymptomatic initially. A prodrome consisting of fever, malaise, and myalgias frequently precedes the onset of pneumonitis (cough and dyspnea). The disease may appear as opacities, nodules, or lobar infiltrates on chest radiographs.29,30

**DIAGNOSTIC TESTING**

Diagnostic imaging in the ED is usually limited to plain film chest radiography and, occasionally, computed tomography (CT). EPs must use caution when prescribing any new medication to transplant patients in the ED because potentially serious drug side effects and drug-drug interactions may result. It is best to discuss medication issues with the patient’s physician or a pharmacist.

Medications commonly used in lung transplant patients are calcineurin inhibitors (e.g., cyclosporine), cell cycle inhibitors, and corticosteroids. Their side effects are listed in Table 53.2. Most patients are maintained on a combination of these classes of medications.

Many commonly used medications may interfere with drugs used for long-term immunosuppression. Medications known to increase the blood levels (and thus toxicity) of certain medications include cyclosporine (Neoral) and tacrolimus (Prograf). In particular, erythromycin, doxycycline, and azole antifungal agents (ketoconazole, fluconazole, itraconazole) all raise serum concentrations of cyclosporine and tacrolimus. In contrast, other medications, such as isoniazid, rifampin, and rifabutin, lower the blood levels of these two immunosuppressants and may put the patient at risk for organ rejection. Sulfonamides, ganciclovir, and acyclovir potentiate the bone marrow toxicity of azathioprine and mycophenolate mofetil.37-40

**IMMUNOSUPPRESSIVE THERAPY**

Because transplant recipients undergo long-term immunosuppressive therapy, they are prone to multiple drug side effects, drug-drug interactions, and higher risk for opportunistic infections. EPs must use caution when prescribing any new medication to transplant patients in the ED because potentially serious drug side effects and drug-drug interactions may result. It is best to discuss medication issues with the patient’s physician or a pharmacist.

Medications commonly used in lung transplant patients are calcineurin inhibitors (e.g., cyclosporine), cell cycle inhibitors, and corticosteroids. Their side effects are listed in Table 53.2. Most patients are maintained on a combination of these classes of medications.

Many commonly used medications may interfere with drugs used for long-term immunosuppression. Medications known to increase the blood levels (and thus toxicity) of certain medications include cyclosporine (Neoral) and tacrolimus (Prograf). In particular, erythromycin, doxycycline, and azole antifungal agents (ketoconazole, fluconazole, itraconazole) all raise serum concentrations of cyclosporine and tacrolimus. In contrast, other medications, such as isoniazid, rifampin, and rifabutin, lower the blood levels of these two immunosuppressants and may put the patient at risk for organ rejection. Sulfonamides, ganciclovir, and acyclovir potentiate the bone marrow toxicity of azathioprine and mycophenolate mofetil.37-40

**TREATMENT AND DISPOSITION**

All patients with suspected lung transplant rejection or infection should be admitted to the hospital for further diagnostic
testing and evaluation. The importance of appreciating the subtle nature of these complications cannot be overemphasized. It is wise to seek consultation with the patient’s pulmonary physician or surgeon. A safe way to evaluate any lung transplant recipient seen in the ED is to assume that infection or rejection is present until proved otherwise (Box 53.5).

Lung transplant recipients are maintained on multiple immunosuppressive medications that interfere with many commonly used medications, such as antibiotics. EPs should never take it on themselves to add a drug to a transplant recipient’s regimen or alter the dose of an immunosuppressant without first consulting with the patient’s physicians.

By understanding the subtleties of rejection and pneumonia and the importance of drug side effects and interactions in lung transplant recipients, the EP will be in a better position to take care of this complex group of patients in the ED.

Chest Pain

Matthew Strehlow and Jeffrey Tabas

Every year 6.2 million people are seen in U.S. emergency departments (EDs) with complaints of chest pain, which accounts for roughly 6% of ED visits and is the second most common reason for such visits. The differential diagnosis of chest pain ranges from benign causes, such as muscle strain, to the immediately life-threatening ones, such as acute coronary syndrome, pulmonary embolism, and aortic dissection. Although the focus in patients with chest pain remains appropriately on life-threatening causes, a majority of patients have benign or indeterminate diagnoses after ED evaluation. In one study of ED patients with symptoms consistent with acute cardiac ischemia, only 8% had acute myocardial infarction (AMI) and 9% had unstable angina.1 Another investigation of patients evaluated in the ED for nontraumatic chest pain found that AMI was diagnosed in 4%, unstable angina or stable coronary disease in 7.5%, and pulmonary embolism or aortic dissection in less than 1%.2 Given the potentially lethal nature of conditions manifested as chest pain and the lack of sensitivity or specificity, in many instances, of the history and physical examination, the emergency physician (EP) must have an organized approach, a complete differential diagnosis, and a thorough understanding of assessment and management of this common complaint.

A differential diagnosis based on anatomic structures within the chest is presented in Box 54.1.

Most patients with nontraumatic chest pain warrant high triage priority and an early electrocardiogram (ECG) (recommended within 10 minutes) to evaluate for AMI. Patient stabilization, evaluation of the history, physical examination, and diagnostic and therapeutic interventions proceed simultaneously. As assessment continues, interventions are refined (Box 54.2). Importantly, the history and physical findings alone are often inadequate to definitively establish or exclude life-threatening diagnoses.

The EP should keep the following points and issues in mind during assessment of a patient with chest pain:

- Use the term discomfort as opposed to pain to facilitate communication.
- Do not ascribe partially reproducible pain to a musculoskeletal cause. Pain arising from inflammation of the pericardium (secondary to AMI or pericarditis) or inflammation of the pleura (pulmonary embolism, pneumonia, or pleurisy) can be partially reproduced by palpation.
- Chest pain that is completely pleuritic (present only on inspiration) or completely reproducible significantly decreases suspicion for cardiac causes and raises suspicion for pulmonary or musculoskeletal causes. Partially pleuritic (worse with inspiration) or partially reproducible chest pain has much less predictive value.

**KEY POINTS**

- Observation and repeated testing are extremely valuable in a patient with chest pain in whom the diagnosis is unclear.
- Rapid ruling out of acute myocardial infarction can be performed with serial cardiac marker testing once an appropriate interval after symptom onset has elapsed (8 hours for troponin I or T), although shorter intervals may be acceptable if immediate stress testing is performed.
- Normal cardiac marker values do not exclude unstable angina.
- Consider life-threatening diagnoses other than acute myocardial infarction in patients with chest pain, including aortic dissection, which is frequently missed and often manifested atypically.

**EPIDEMIOLOGY**

In the differential diagnosis of patients with chest pain, one must consider the five groups of structures in the thorax: cardiac (heart and pericardium), pulmonary (lungs and pleura), gastrointestinal (esophagus and upper abdominal contents), vascular (aorta and great vessels), and musculoskeletal (chest wall). Chest discomfort is experienced through three distinct pathways, as follows:

Visceral pain, from internal structures such as the heart, lungs, esophagus, and aorta, may be difficult for the patient to define or localize. It is experienced as discomfort or a vague sensation and is often difficult to pinpoint.

Somatic pain, from chest wall structures and the parietal pleura, is often easier to describe and localize. Somatic pain may be sharp or stabbing and exacerbated by movement or position.

Referred pain, from irritation or inflammation of the upper abdominal contents, is a form of visceral pain that may be perceived in the chest wall, shoulder, or upper part of the back.

**PATHOPHYSIOLOGY**

In the differential diagnosis of patients with chest pain, one must consider the five groups of structures in the thorax.

BOX 54.2 Approach to Patients with Chest Pain

**Initial Assessment (<10 Minutes)**
- ABCs: airway, breathing, and circulation
- Patient appearance
- Vital signs, O₂ saturation
- Electrocardiogram
- Directed history and physical examination
  - If the patient appears ill, the history raises concerns, vital signs are abnormal, or the electrocardiogram shows evidence of ischemia, the following actions should be taken:
    - Establishment of intravenous access
    - Cardiac monitoring
    - O₂ administration if low O₂ saturation or shortness of breath is present
    - Immediate subsequent assessment (as follows)

**Subsequent Assessment**
- Aspirin, 325 mg orally (unless ischemia is excluded or aspirin is contraindicated)
- Complete history and physical examination
- Radiographic, laboratory, and further electrocardiographic evaluation as indicated

- Substantial evidence suggests that responses to treatments such as sublingual nitroglycerin or a “gastrointestinal cocktail” do not differentiate the etiology of the chest pain.
- Do not overestimate the value of low-risk features when high-risk features are present (i.e., pain that is completely pleuritic but radiates to the left arm should still raise concern for possible acute coronary syndrome).
- The history and physical examination of patients with non-specific chest pain are inadequate to justify discharge without further evaluation.

**EPIDEMIOLOGY**

Several risk stratification systems have been proposed for acute coronary syndrome. These systems have been shown to help in risk stratification, thereby enabling triage decisions. They have never been shown to improve the ability to formulate discharge decisions in comparison with practitioner judgment. The American College of Cardiology and the American Heart Association have published criteria to determine a patient’s risk for coronary artery disease and adverse outcomes from acute coronary syndrome. These guidelines are cumbersome and more appropriately applied to patients with documented disease than to undifferentiated ED patients. A simplified approach to stratifying risk is to determine whether the patient has definite acute coronary syndrome, probable acute coronary syndrome, or possible acute coronary syndrome, as follows:

- Patients with definite acute coronary syndrome are those with (1) changes diagnostic of ischemia or infarction on an ECG, (2) diagnostic elevation of serum cardiac markers, or (3) evidence of new heart failure or shock directly attributable to an acute ischemic event.
- Patients with probable acute coronary syndrome are those in whom suspicion for acute coronary syndrome is high but definitive criteria are lacking. An example is a patient with a classic history for acute coronary syndrome or whose cardiac marker values are slightly elevated but still below the diagnostic cutoff and who does not have clear ECG evidence of ischemia.
- Patients with possible acute coronary syndrome constitute the majority of patients with chest pain. They have atypical histories, their ECG findings are normal or unchanged from previous studies, or suspected alternative causes are triggering their symptoms.
This chapter is focused on patients with possible acute coronary syndrome. After chest radiography, a substantial proportion of such patients require further testing and observation, such as serial cardiac biomarker testing or other tests to evaluate for alternative diagnoses.

The challenge for the EP lies in determining when and which patients with possible acute coronary syndrome can be safely discharged home. At this time no definitive answer exists. A critical error, however, is failure to identify features that warrant further evaluation. Characteristics such as advanced age, known coronary artery disease, diabetes, pain similar to that of a previous myocardial infarction, worsening of typical angina, pressurelike or squeezing discomfort, and radiation of pain to the neck, left shoulder, or left arm have all been shown to increase the likelihood of AMI.

### PRESENTING SIGNS AND SYMPTOMS

The classic manifestation of AMI is discomfort that feels like an elephant sitting on one’s chest; radiates to the left shoulder, arm, or jaw; and is associated with shortness of breath, nausea, or diaphoresis. Patients may describe their discomfort with a clenched fist against their chest, a finding known as the Levine sign. Physical examination demonstrates tachycardia, diaphoresis, and if the infarction has compromised left ventricular function, findings of acute heart failure such as hypoxia, tachypnea, elevated jugular venous pulsations, and bilateral rales. The classic manifestation in patients with unstable angina is a sense of discomfort or pressure that is similar to that of AMI but transient in nature. Patients with unstable angina experience similar associated symptoms typically brought on by exertion and relieved with rest or nitroglycerin. In practice, these classic findings are the exception, not the norm.

Risk factors for coronary artery disease predict a patient’s risk for the development of ischemic heart disease over a period of many years but are only moderately predictive of acute coronary syndrome in the ED. Most important, it is well established that a lack of cardiac risk factors by itself does not place a patient at low risk for acute cardiac events.

Historical and examination features that raise or lower the likelihood of acute coronary syndrome are described in Box 54.3 and Table 54.1. It is important to remember that the presence of lower-likelihood features does not exclude the diagnosis of acute coronary syndrome. One study of patients with AMI found that 22% had sharp or stabbing pain and 13% had partially pleuritic pain.5

The physical examination should be thorough, and findings suggestive of an alternative diagnosis may be helpful but are often not adequately specific to exclude acute coronary syndrome. For example, in 7% of patients with AMI, the pain is fully reproduced by palpation.5

### DIAGNOSTIC TESTING

In adult patients with chest pain or acute coronary syndrome equivalents, an ECG is recommended within 10 minutes of ED arrival. Thirty percent to 50% of patients with AMI have diagnostic ECG findings, 40% to 70% have nonspecific ECG findings, and 1% to 10% have normal ECG findings. Nonspecific or unchanged ECG findings do not affect the likelihood of acute coronary syndrome; although a normal ECG does not exclude acute coronary syndrome, it significantly decreases the likelihood. Comparing the ECG with previous or serial ECGs can improve sensitivity and specificity. A right-sided ECG is recommended in all patients with inferior ST changes, and a posterior lead ECG is recommended if ST depression is present in septal leads V1 through V3. The ECG helps guide not only diagnosis but also therapy decisions (i.e., the presence of ST-segment elevation in AMI is a primary criterion for thrombolytic therapy). As with all tests, it is imperative that the ECG findings be interpreted in context.

An understanding of cardiac biomarkers is pivotal to excluding possible AMI in the ED. Currently, AMI is defined as the rise and fall of serum cardiac biomarkers in the presence of at least one of three other findings: ischemic symptoms, a pattern of progressive ischemic changes on ECG, or imaging evidence of a new regional wall motion abnormality.

*The American College of Emergency Physicians recommends an initial measurement of cardiac markers and a second measurement at the given intervals for rapid exclusion of MI in low- to moderate-risk patients. It is unclear whether a second measurement is needed if the time between symptom onset and the patient’s arrival at the ED exceeds the recommended interval for the second measurement. See Fesmisse FM, Decker WW, Diercks DB, et al. Clinical policy: critical issues in the evaluation and management of adult patients with non–ST-segment elevation acute coronary syndromes. Ann Emerg Med 2006;48:270-301.

Current guidelines recommend the use of cardiac troponins for the evaluation of all patients with suspected acute coronary syndrome. Troponins, regulatory proteins found in cardiac muscle, are composed of three subunits: I, T, and C. Cardiac subunits I and T are genetically distinct from the skeletal muscle forms, and no cross-reactivity occurs on immunoassays. Within 2 to 8 hours of AMI, troponin levels are abnormal and remain so for 7 to 10 days (Table 54.2). Detectable troponin but at a value below the diagnostic cutoff for AMI still portends a higher risk for adverse outcomes. Nonspecific elevations, especially of troponin T, can occur with renal dysfunction, pulmonary embolism, septic shock, decompensated heart failure, myocardial contusion, pericarditis, and myocarditis. Cardiac troponins are more sensitive and specific than creatinine kinase, MB fraction (CK-MB), and myoglobin for cardiac muscle damage, and contemporary troponin assays identify the majority of AMIs within 3 hours, thus limiting the utility of CK-MB and myoglobin.

CK-MB is an enzyme present at higher percentages in cardiac muscle than in skeletal muscle, and it is relatively specific for cardiac muscle damage. False-positive results occur in patients with renal failure and in those with large amounts of skeletal muscle injury, such as seen with rhabdomyolysis. The CK-MB index improves the specificity of the biomarker by comparing the ratio of CK-MB with total CK. Values higher than 5% are consistent with AMI, whereas those from 3% to 5% are indeterminate. CK-MB is detectable in blood 3 to 8 hours after myocardial infarction and returns to normal within 48 to 72 hours (see Table 54.2). The CK-MB subforms CK-MB1 and CK-MB2 rise earlier than CK-MB and are detectable 1 to 3 hours after injury, with a sensitivity of 92% achieved at 6 hours. Unfortunately, laboratory testing for CK-MB1 and CK-MB2 is not widely available.

Myoglobin is a heme protein in skeletal and cardiac muscle whose levels rise rapidly within 2 to 4 hours and return to normal within 24 to 36 hours. Its utility is limited by inadequate sensitivity and specificity, and its measurement is primarily used in combination with that of CK-MB and troponin as a point-of-care “triple-marker” assay. Studies have demonstrated that specificity can be improved through evaluation of the rate of myoglobin elevation (delta myoglobin) over a 1- to 2-hour period. It is recommended that delta myoglobin cutoff values of 25% to 40% be used to indicate abnormality. Other cardiac markers are being investigated, and their roles are being determined.

Recommendations based on the best available evidence and consensus argue against using a single cardiac marker value within 6 hours of the onset of symptoms to exclude AMI. For patients initially seen more than 6 to 8 hours after onset of the most recent episode of pain, a single negative cardiac marker value is often adequate to exclude AMI (but not unstable angina) in those with possible acute coronary syndrome. A period of observation that includes repeated ECG and serum CK-MB and troponin measurements can be used to rapidly rule out AMI at 6 and 8 hours after the onset of symptoms, respectively (see Table 54.2). Some evidence shows that a more accelerated testing approach is appropriate when such testing is followed immediately by stress imaging. In fact, one investigation found that it was safe to test patients with chest pain on an exercise treadmill immediately without initially determining cardiac marker values. The patients involved in this study, however, were at extremely low risk, with normal or nearly normal ECG findings, no evidence of heart failure, and the ability to exercise, and they were found to have only a 1% rate of AMI.

**OBSERVATION UNITS AND PROTOCOLS**

Increases in resource utilization, cost, and medicolegal concerns associated with patients evaluated in the ED for chest pain have led to the advent of rapid assessment protocols and chest pain units. These strategies aim to lower admission rates and cost of care while minimizing the inappropriate discharge of patients with unrecognized acute coronary syndrome. Approaches vary widely in these strategies, and most published methodologies involve immediate stress testing of low- to moderate-risk patients after a period of observation with serial ECGs and cardiac marker testing. Protocol-driven strategies increase the number of patients evaluated, accelerate the rate of evaluation, lower the number of missed events, and may save overall costs.

After a period of observation, repeated cardiac marker testing, and either continuous or intermittent ECG
monitoring, patients in whom the ECG findings are unremarkable and cardiac biomarker results are negative undergo stress testing. Guidelines recommend that the stress test be performed within 72 hours of ED discharge; a majority of published reports describe stress testing before discharge.1

The most common adjunctive test is the continuous ECG treadmill stress test (TST). Patients with normal TST results under these circumstances have been found to have acceptably low rates of missed ischemia and adverse events. Unfortunately, a reasonable percentage of patients are poor candidates for an ECG TST (18% in one study) because of either an inability to ambulate at a moderate (2.5 mph) pace or the presence of confounding baseline ECG findings, such as left ventricular hypertrophy, left bundle branch block, ventricular-paced rhythm, or preexcitation syndrome. ECG TSTs also have a 5% to 25% nondiagnostic rate, depending on the patient population and protocol used. Patients in whom the ECG TST cannot be used must undergo stress imaging studies. Patients with nondiagnostic or abnormal ECG TST results should undergo further evaluation, which usually requires admission.

Although the percentage of low-risk chest pain patients in whom acute coronary syndrome is diagnosed during their hospital evaluation is low, 0.5% to 5%, the admission rate of patients who have been evaluated in a chest pain unit ranges from 10% to 50%. Patients discharged after a rapid assessment protocol or evaluation in a chest pain unit should receive outpatient follow-up soon.

TREATMENT

Patients with possible acute coronary syndrome should receive aspirin. In patients with ongoing ischemic symptoms, nitrates may be given. Nitrates have never been shown to improve outcomes in patients with acute coronary syndrome, and recently, the response to nitrates has been shown to lack predictive value in the diagnosis of acute coronary syndrome. Their use in these low-likelihood patients should be weighed against the risk for hypotension or even headache. Analgesics such as morphine are given to patients with discomfort unresponsive to nitrates. Controversy surrounds the use of β-adrenergic receptor blockers. Currently, routine administration of intravenous beta-blockers in the prehospital setting or ED is not recommended.4 Therapies such as heparin, clopidogrel, and glycoprotein IIb/IIIa inhibitors have been shown to be of benefit primarily in patients with definite acute coronary syndrome and therefore should not be used in this low-likelihood group.4

DISPOSITION

It is important to acknowledge that the clinician cannot obtain perfect sensitivity in the assessment of patients with any disease. An analysis of multiple studies on acute coronary syndrome found that clinicians missed fewer AMIs when they admitted more patients.9 Clearly, there is a limit to this strategy, although evidence does suggest that providing resources to increase the number of patients undergoing evaluation may reduce the proportion of acute coronary syndrome that is missed. This appears to be a cost-effective approach but depends on multiple factors that may be outside the clinician’s and even the institution’s control. Even when clinicians are confident of an alternative diagnosis, subsequent adverse cardiac events may occur, with a 2.8% rate documented in one large study.19 The acceptable “miss rate” depends on the following factors:

- Risk aversion of the clinician
- Risk aversion of the patient
- Resources available
- Perceived risk of litigation for an adverse outcome even when the care is appropriate

Even patients with chest pain who undergo thorough evaluation that yields unremarkable findings experience a low but meaningful rate of adverse events. On the basis of these considerations, clinicians must decide the level of acceptable risk for missed acute coronary syndrome while realizing there is a finite rate of adverse outcomes. It is best for the EP to explain these risks to the patient, clearly document the reasoning, clearly document the patient’s understanding, provide appropriate discharge instructions, and document the recommendations for follow-up.

AORTIC DISSECTION

Aortic dissection is a tear in the intimal lining of the aorta. It is a distinct entity from a dilated aortic aneurysm, which involves pathologic dilation of the intima, media, and adventitia and can result from traumatic aortic injury. The reported incidence is 2.9 cases per 100,000 patients per year, which corresponds to roughly 5000 new adult cases per year in the United States. Missing or incorrectly diagnosing this condition can be fatal, especially if anticoagulation or fibrinolysis is initiated. Risk factors for aortic dissection include hypertension, Marfan disease, pregnancy, valvular disease, syphilis, and cocaine use.

PRESENTING SIGNS AND SYMPTOMS

The classic manifestation of aortic dissection is acute (with maximum intensity at onset), severe, tearing chest pain that radiates to the back in patients with a history of hypertension. On examination, patients may exhibit pulse deficits or an aortic insufficiency murmur. Unfortunately, the classic manifestation is the exception and the clinical spectrum is broad (Table 54.3). Symptoms frequently mimic more common disorders, and the clinician must maintain a high index of suspicion.13

No single finding or combination of findings has been determined to be sensitive or specific enough to direct the evaluation for aortic dissection. Given that the diagnosis is frequently missed, the EP should have a low threshold for evaluating patients for aortic dissection when it is part of the differential diagnosis. Aortic dissection should be considered in a patient with any of the following features:

- Severe chest pain
- Pain that occurs in more than one anatomic distribution (chest and back, chest and abdomen)
- Pain accompanied by a focal neurologic complaint
DIAGNOSTIC TESTING

Chest radiography alone is insufficient to exclude aortic dissection. However, normal findings on chest radiography significantly decrease the level of suspicion—as long as they are truly normal; only 12% of chest radiographs in patients who do have aortic dissection are retrospectively considered normal. In 78% of patients with aortic dissection, chest radiography demonstrates either a widened mediastinum or abnormal aortic contour. If possible, the EP should inform the radiologist that aortic dissection is under consideration to direct examination of the radiograph toward the pertinent abnormalities.

The following features are found on the chest radiographs of patients with aortic dissection:

- Wide mediastinum or abnormal aorta (in 78% of cases)
- Normal mediastinum and aorta (12.5%)
- Wide paraspinal shadow
- Pleural effusion
- Tracheal shift
- Calcification displacement
- “Lump” distal to vessels

ECG findings are neither sensitive nor specific for the diagnosis. In fact, as many as one in six patients with aortic dissection have evidence of ischemia or AMI on an ECG—presumably resulting from occlusion of the coronary vessels by an intimal flap or thrombosis—and 70% have normal or nonspecific findings.

Helical computed tomography and echocardiography provide definitive testing for aortic dissection. Either diagnostic test is 95% to 100% sensitive; echocardiography is preferred when the patient is unstable because it can be performed in the critical care setting. Transthoracic echocardiography is extremely sensitive in detecting abnormalities of the aortic root and ascending aorta, whereas the transesophageal approach is required to exclude involvement of the arch or descending aorta (Fig. 54.1).

TREATMENT

The goal of initial ED treatment of patients with aortic dissection is to decrease shearing stress on the aorta with negative inotropic and chronotropic agents, such as intravenous beta-blockers or calcium channel blockers. Further blood pressure control can be achieved with intravenous nitroprusside or nitroglycerin. Desired values are a heart rate of 50 to 60 beats/min and a systolic blood pressure of 100 to 110 mm Hg.

DISPOSITION

Once aortic dissection is confirmed, ED medical management proceeds in parallel with emergency surgical evaluation, and if surgery is deemed appropriate, arrangements for intervention should not be delayed.

COCAINE-ASSOCIATED CHEST PAIN

The U.S. Department of Health and Human Services reported in 2002 that 33 million people 12 years and older (14.4% of the U.S. population) reported using cocaine at least once in their lifetimes. Cocaine abuse is not limited to a specific subset of the population and is frequently seen in ED patients, as demonstrated by an urban ED report that 2% of the institution’s patients 60 years and older tested positive for cocaine.
PATHOPHYSIOLOGY

Chest pain, the most common complaint of ED patients with cocaine-associated visits, results from myocardial ischemia, trauma, pulmonary damage, and probably nonspecific vaso-spasms. Cocaine raises the risk for myocardial ischemia via multiple factors, including α-adrenergic receptor–mediated coronary vasoconstriction, platelet aggregation, direct myocardial toxicity, accelerated atherosclerosis, and increased myocardial oxygen demand. Therefore, acute coronary syndrome may be present in individuals who would otherwise be considered to have a very low risk for the disorder.

PRESENTING SIGNS AND SYMPTOMS

Inquiry should be made about recent cocaine use in all patients seen in the ED with chest pain. Patients who have used cocaine recently often have significant elevations in blood pressure in addition to their chest pain. They may be jittery and somnolent at the same time after having binged on crack cocaine. Studies have documented the incidence of AMI in patients with cocaine-associated chest pain to be approximately 6%. One study found that patients with cocaine-associated AMI were young (mean age, 38 years), tobacco smokers (91%), and nonwhite (72%) and had used cocaine within the proceeding 24 hours (88%). Nevertheless, a significant proportion of patients with cocaine-associated chest pain are older, and their risk for myocardial ischemia, though greatest in the first hours after the drug use, remains elevated for at least 2 weeks after discontinuation of the drug.

MEDICAL DECISION MAKING AND DIFFERENTIAL DIAGNOSIS

The chest pain or dyspnea associated with cocaine use may stem from a variety of causes. In addition to acute coronary syndrome, aortic dissection has been reported to be associated with cocaine use. The barotrauma induced by smoking crack cocaine results from deep inhalation followed by the Valsalva maneuver or severe coughing and leads to pneumothorax, pneumomediastinum, and pneumopericardium. Pulmonary diseases associated with smoking cocaine include noncardiogenic pulmonary edema, pneumonia, asthma, interstitial lung disease, bronchiolitis obliterans–organized pneumonia, parenchymal hemorrhage, and pulmonary vascular disease. Musculoskeletal trauma may also occur.

DIAGNOSTIC TESTING

The initial evaluation of a patient with chest pain is the same regardless of whether cocaine is involved. The EP should order laboratory testing of blood, an ECG, and chest radiography for similar indications. The ECG findings do not depend on whether the AMI is cocaine related. In both those with and those without cocaine-related AMI, ECG findings are normal in 1% to 10%, nondiagnostic but abnormal in 30% to 50%, and diagnostic in 50% to 60%. Nonspecific abnormalities and normal variations often found in young persons, such as J-point elevation and left ventricular hypertrophy, are common.

Testing for the myocardial markers troponin and CK-MB is the cornerstone of evaluation for AMI in patients with cocaine-associated chest pain. Troponins are the markers of choice because unlike CK-MB, they are not affected by recent cocaine use. The extent to which skeletal muscle breakdown from cocaine use affects the diagnostic accuracy of CK-MB measurement has not been established.

Stress testing in patients with cocaine-associated chest pain after appropriately timed myocardial marker testing to evaluate for AMI is considered safe. The utility of exercise ECGs, myocardial perfusion, or stress echocardiography may be limited, however, given the low rate of reversible coronary artery lesions in these patients (2% to 14%) and the significant false-positive rate.

TREATMENT AND DISPOSITION

Initial management (cardiopulmonary monitoring and aspirin) of patients with cocaine-associated chest pain is similar to that for patients with typical chest pain. In addition, the use of short-acting benzodiazepines, such as lorazepam, 1 mg intravenously repeated as necessary, in combination with nitroglycerin is recommended to counteract the sympathomimetic effects of cocaine. Hypertension usually responds to the preceding treatments. Additional blood pressure control is occasionally required because of suspicion for end-organ damage. β-Adrenergic blockade raises the theoretic concern of worsening hypertension as a result of vasospasm from unopposed α-adrenergic stimulation; however, little evidence supports this potential complication. Finally, for patients with evidence of cardiac ischemia or infarction, cardiac catheterization is beneficial and is preferred over thrombolytics, which should be used with caution.

There is some controversy regarding the disposition of patients with cocaine-associated chest pain. The EP should maintain a low threshold in evaluating for aortic dissection if the symptoms are severe and persistent. For patients in whom the findings are unremarkable—no ECG evidence of ischemia, no elevation in serial cardiac markers, and symptoms that resolve with treatment during observation—many authorities would argue that discharge is safe. Preliminary evidence has shown that this population is at low risk for subsequent complications. Until this issue is studied systematically, however, whether patients with cocaine-associated chest pain should be admitted for further evaluation is unclear.

REFERENCES

Ischemic heart disease occurs as a result of coronary artery disease and does not discriminate on the basis of gender, ethnicity, or race. Ischemic heart disease remains the leading cause of death in the United States and is responsible for more than half a million deaths annually—despite the marked advances over the past 5 decades in prevention as well as diagnosis and treatment of coronary artery disease. Advances include a reduction in smoking rates; improvements in the management of diabetes, hypertension, and hyperlipidemia; use of aspirin and other antiplatelet agents as both primary and secondary prevention; and improvements in the acute management of acute coronary syndrome (ACS). The last factor has evolved significantly, beginning with the advent of cardiac monitoring and the development of external cardiac defibrillators in the 1950s and progressing to widespread use of external cardiac massage and cohorting of patients with ACS within coronary care units in the 1960s. Pharmacologic developments in the management of ACS began with the use of beta-blockers and aspirin and advanced rapidly to include more sophisticated antiplatelet and anticoagulant agents.

The 1980s brought the widespread use of fibrinolytic therapy and ushered in the reperfusion era of therapy for ACS. Also in the 1980s, coronary angiography was first performed in the setting of acute myocardial infarction (MI) and demonstrated occlusion of the infarct-related artery (IRA), and mechanical interventions were subsequently developed to open the artery, beginning with balloon angioplasty and evolving to more sophisticated techniques such as stenting, thrombectomy, and atherectomy. All these advances have led to a significant decline in the overall age-adjusted mortality of patients with ischemic heart disease, primarily because of a diminution in both the incidence and case fatality rate of acute MI.

Nonetheless, the burden of ACS remains significant both from a health care perspective and from an economic perspective. More than 1 million acute MIs occur in the United States annually, and 20% of affected patients die before reaching the hospital, primarily from arrhythmias during the first hours of symptoms. Many survivors of acute MI are left with impaired cardiac function, which adversely affects their ability to perform activities of daily living and their quality of life. Approximately 6 million emergency department (ED) visits in the United States are made annually for the evaluation of chest pain, and as many as one in three of these patients are ultimately found to have ACS. The annual cost of providing care for patients with ACS, both immediately and then later for those who survive, is more than $100 billion. Finally, despite advances in diagnostic techniques, 2% to 5% of patients with acute MI are discharged from the ED because their disease is not identified. These “missed MI” patients represent the highest mean payments for emergency medicine–related medical malpractice claims.
but is due to coronary vasospasm rather than unstable coronary atherosclerotic plaque. It may be manifested as ST-segment elevation on an electrocardiogram (ECG) and mimic ST-segment elevation myocardial infarction (STEMI) but generally responds to nitroglycerin with resolution of the acute ECG abnormalities.

Myocardial infarction is defined as myocardial necrosis. Clinical criteria for the presence of an acute, evolving, or recent MI, which have been laid out jointly by the American College of Cardiology and the European Society of Cardiology, focus on any evidence of myocardial cell death. The exact definition of an acute or evolving MI is a rise above the upper limit of normal and subsequent fall in levels of cardiac biomarkers specific for myocardial necrosis (troponin or the MB fraction of creatine kinase MB [CK-MB]) along with at least one of the following:

- Symptoms consistent with ACS
- ECG evidence of myocardial ischemia, specifically, ST-segment elevation or depression or T-wave inversions
- Development of pathologic Q waves on the ECG
- Percutaneous coronary artery intervention

Myocardial infarction is further classified as STEMI and non-ST-elevation MI (NSTEMI). STEMI is present when the patient has (1) cardiac biomarkers for necrosis as previously defined and (2) new or presumed new ST-segment elevation in two or more contiguous ECG leads. The cutoff point for ST-segment elevation is 0.1 mV. Contiguous leads are defined in the chest leads as V1 through V6 and in the frontal plane as the sequence aVL, I, inverted aVR, II, aVF, and III. Patients who meet the clinical criteria for STEMI and left bundle branch block (LBBB) and are not old or who have ECG evidence of an isolated true posterior MI are also considered, for treatment algorithm purposes, to have STEMI. NSTEMI is present when the patient meets the criteria for MI as previously defined but exhibits no evidence of ST-segment elevation, new LBBB, or ECG evidence of an isolated posterior wall MI.

Acute coronary syndrome is the clinical manifestation of acute myocardial ischemia resulting from the presence of unstable coronary plaque. Accordingly, ACS is represented by the full spectrum of STEMI, NSTEMI, and UAP, which comprise a continuum of similar clinical and pathophysiologic features. STEMI and NSTEMI are differentiated by the findings on a 12-lead ECG, whereas UAP is identical to NSTEMI except that the cardiac biomarkers remain normal in the former. Given that a laboratory result is the only distinguishing feature between patients with UAP and those with NSTEMI, patients are treated identically on arrival by the initial health care provider.

PATHOPHYSIOLOGY

The pathophysiology of acute myocardial ischemia is related to an imbalance between myocardial oxygen supply and demand. Specifically, myocardial ischemia occurs when coronary perfusion is insufficient to meet myocardial oxygen consumption needs. Myocardial oxygen needs depend on the heart rate, afterload conditions, and contractility of the myocardium. Insufficient coronary perfusion is generally due to atherosclerosis involving the coronary arteries. In patients with chronic stable angina, fixed atherosclerotic lesions partially obstruct flow of blood to the myocardium; when demand for oxygen increases (e.g., because of exercise), flow may become insufficient to meet the demand, and myocardial ischemia and anginal symptoms occur.

The pathophysiology of ACS begins when an atherosclerotic plaque within a coronary artery becomes unstable as a result of plaque rupture or hemorrhage into the plaque. The atherosclerotic plaque need not be causing critical stenosis before becoming unstable. Plaque rupture or hemorrhage exposes the lipid-rich core of the plaque and the basement membrane proteins of the blood vessel wall. As part of the resultant inflammatory cascade, platelets adhere to the core of the ruptured plaque and start to release platelet agonists—adenosine diphosphate, thrombin, and epinephrine. These agonists induce platelet activation, which is characterized by the expression of 50,000 to 80,000 glycoprotein (GP) IIb/IIIa receptors on the surface of each platelet. Fibrinogen, freely circulating in the bloodstream, is a bivalent molecule with binding sites on each end that are specific for the GP IIb/IIIa receptor. Fibrinogen thus facilitates platelet aggregation because each strand cross-links two platelets. The resultant platelet-fibrinogen web is further stabilized by thrombin, which is released by activated platelets and by activation of the coagulation cascade. Thrombin cross-links and modifies fibrinogen to the more stable fibrin.

As the platelet-fibrin aggregation grows, it traps red and white blood cells moving through the coronary artery, and a thrombus forms. At the same time, the inflammatory process leads to the release of vasoactive mediators, which may induce vasospasm, further compromising coronary blood flow. If this process leads to complete occlusion of the epicardial coronary artery at the site of plaque rupture, STEMI will result. If the thrombus is partially obstructing coronary blood flow and generating microemboli to smaller coronary arterioles, which in turn may become obstructed or exhibit spasms, NSTEMI (if myocardial cell death has occurred as shown by a rise in cardiac biomarkers) or UAP (if biomarkers remain normal) results.

Much less commonly, ACS may be due to primary vasospasm rather than primary plaque rupture. Generally the result of sympathetic overstimulation by endogenous epinephrine or serotonin, coronary vasospasm may lead to platelet activation and thrombus formation, even in the absence of underlying coronary artery atherosclerosis. Coronary vasospasm is more likely to cause UAP than MI.

PRESENTING SIGNS AND SYMPTOMS

HISTORY

Patients with ACS classically have chest discomfort in the substernal (precardial) area. Typically, this discomfort is described as pain, pressure, or tightness and may begin at rest or during exertion. It may also be located in the left or right anterior portion of the chest and may radiate to the shoulder, neck, jaw, arm, or back. Characteristically, the duration of discomfort ranges from several minutes to an hour. It is rare for the discomfort related to ACS to last only seconds or to persist continuously for hours. Associated symptoms that may be present are dyspnea, nausea, vomiting, diaphoresis, weakness, dizziness, and fatigue.
ATYPICAL PRESENTATIONS

The emergency physician (EP) should beware of atypical manifestations of ACS, which are common and portend a markedly worse clinical outcome. The quality of the chest discomfort cannot be relied on to exclude ACS. Patients with discomfort that is sharp or stabbing in quality or is pleuritic, palpable, or positional in nature make up a significant minority of patients with ACS. Furthermore, any of the associated symptoms listed previously can occur either alone or together without chest discomfort and still represent ACS. Findings of this type (without chest discomfort) are referred to as an anginal equivalent and require the same clinical management as cases manifested more classically. Other atypical manifestations include isolated back, neck, jaw, or arm discomfort; epigastric pain or burning; indigestion; isolated dyspnea; and generalized weakness. Elderly patients are particularly likely to have atypical symptoms, in particular, weakness and altered mentation. Other populations in whom ACS is likely to be manifested atypically are women, nonwhite patients, and diabetic patients. In all these groups ACS is much more likely to be misdiagnosed initially than in the overall population.

PHYSICAL FINDINGS

Physical examination is often unrevealing in patients with ACS because most of the findings are related to complications of ACS. The vital signs should be evaluated carefully and monitored for evidence of arrhythmia, respiratory compromise, and cardiogenic shock. Jugular venous distention, rales, and a third heart sound (S₃) are signs of congestive heart failure complicating ACS. When these signs are coupled with altered mental status and hypotension, cardiogenic shock is likely.

Physical findings can also help suggest an alternative diagnosis. For example, fever and signs of consolidation on lung examination are suggestive of pneumonia rather than ACS, whereas unilateral absence of breath sounds suggests pneumothorax as the most likely diagnosis. Although chest wall tenderness is suggestive of a musculoskeletal etiology, ACS should not be excluded as a diagnosis solely on the basis of chest discomfort that is reproducible on palpation.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis in patients with ACS includes a host of other diseases that can be manifested as chest pain or dyspnea: stable angina, pericarditis, myocarditis, pulmonary embolism (PE), aortic dissection, pneumonia, pleurisy, pneumothorax, Boerhaave syndrome, esophageal reflux, esophageal spasm, gastritis, biliary colic, pancreatitis, peptic ulcer disease, musculoskeletal pain, and herpes zoster. One of the historical features that tends to favor a diagnosis of ACS is chest pressure or tightness rather than a sharp pain, which is more commonly associated with pericarditis, pleurisy, pneumothorax, PE, and aortic dissection. In addition, the chest discomfort in patients with ACS tends to gradually worsen, unlike the pain associated with PE or aortic dissection, which is generally worst at the onset and then persistently severe. Pain of a pleuritic nature tends to favor PE, pleurisy, or pneumothorax, whereas pain that is worse on palpation tends to suggest a chest wall musculoskeletal cause. Discomfort that is positional in nature tends to favor pericarditis or gastrointestinal causes rather than ACS. However, it is very important to remember that a significant percentage of patients with ACS have pleuritic, positional, or palpable chest pain and that these historical features cannot be used to exclude the diagnosis.

Although the differential diagnosis of chest discomfort is long and includes entities from several different organ systems, some bear special mention because of the risk that they pose to patients. In each patient with chest discomfort, the EP should consider and reasonably exclude aortic dissection, PE, pneumonia, pneumothorax, and Boerhaave syndrome. This does not mean that these diagnoses must be excluded by definitive diagnostic techniques. They may be reasonably excluded on the basis of the history and physical findings, but this thought process should be documented clearly in the medical record.

DIAGNOSTIC TESTING

ELECTROCARDIOGRAM

The 12-lead ECG is the most important diagnostic test for patients with suspected ACS. In addition to providing diagnostic information, the ECG can be used to assess progression of the syndrome and response to therapeutic interventions. In addition, ECG findings determine treatment pathways and assist with disposition decisions. The ECG in patients with suspected ACS should be carefully and systematically analyzed for evidence of ST-segment elevation, ST-segment depression, T-wave inversion, and pathologic Q waves as signs of myocardial ischemia or infarction. Also, the rate, rhythm, and intervals, along with QRS morphology, should be studied for evidence of complications of ACS. Finally, evidence of noncardiac causes of chest pain should be sought on the ECG, in particular, findings suggestive of PE and pericarditis.

It important to remember that many patients with confirmed ACS have normal or nondiagnostic findings on the ECG. Even in patients with acute MI, the ECG findings can be normal in a small percentage of cases. In addition, the ECG represents only one static point in time, and ACS is a dynamic process. Hence, a single nondiagnostic ECG cannot be relied on to exclude the diagnosis of ACS, and the history elicited from the patient remains more important than findings on the ECG, particularly when they are negative or nondiagnostic. Nonetheless, specific ECG findings of myocardial ischemia or infarction are often present and are very helpful in determining treatment and disposition.

Electrocardiographic Findings in ST-Segment Elevation Myocardial Infarction

The initial ECG abnormality that occurs in patients with epicardial coronary artery occlusion is peaked hyperacute T waves in the distribution supplied by the IRA. T waves become tall and sharply peaked within minutes of occlusion of the IRA (Fig. 55.1, A). Peaked T waves may also be seen in patients with hyperkalemia, pericarditis, early repolarization, and LBBB. In the next several minutes, ST-segment elevation becomes evident on the ECG (see Fig. 55.1, B). To be diagnostic, the ST-segment elevation must be at least 1 mm above the baseline; this is generally considered the TP segment.
Fig. 55.1  A, An initial electrocardiogram (ECG) obtained shortly after the onset of symptoms shows hyperacute peaked T waves in leads V₂ through V₅, consistent with early anterior transmural injury current. B, A second ECG obtained several minutes later shows hyperacute T waves and ST-segment elevation in the precordial leads along with ST-segment elevation in leads 1 and aVL, consistent with acute anterolateral myocardial infarction secondary to proximal occlusion of the left anterior descending coronary artery.
Most typically, this ST elevation is convex or domed, though less commonly it may be straight or, rarely, concave. Concave ST-segment elevations are more characteristic of other conditions associated with ST-segment elevation (Box 55.1).

In addition to the clinical situation, a factor distinguishing STEMI from other conditions is the dynamic nature of the ST-segment changes with STEMI; serial ECGs commonly show waxing and waning ST-segment elevation. Hours to days later, the ST segments return toward baseline, the T waves invert, and pathologic Q waves develop in areas of the ECG that correspond to the IRA. The location of the ST elevations and other findings on the ECG generally correspond to the anatomic location of the myocardium and the associated IRA. Anterior infarctions exhibit ST elevation in leads V₁ through V₄ (Fig. 55.2). Findings in leads V₁ and V₂ indicate involvement of the septum. MIs with these findings are caused by occlusion of the left anterior descending (LAD) coronary artery. When additional ST elevations are seen in leads V₅, V₆, I, and aVL, the location of the LAD occlusion is probably proximal to the first diagonal branch, which causes an anterolateral infarction (see Fig. 55.1, B). Inferior infarctions are characterized by ST elevations in leads II, III, and aVF (Fig. 55.3, A) and are due most commonly to right coronary artery (RCA) occlusion. Reciprocal ST depressions may be present in leads I and aVL.

Inferior MIs are associated with concomitant right ventricular infarction, which can be evident on right-sided ECG leads, particularly in RV₄ and RV₅ (see Fig. 55.3, B). Inferior MIs are also frequently associated with posterior wall involvement, which is seen on the ECG as ST depressions in leads V₁ through V₃ and, on occasion, early R-wave progression with tall R waves in leads V₁ through V₃ (Fig. 55.4).

Isolated posterior MIs, the rarest of transmural MIs, are the most easily misdiagnosed because the 12-lead ECG may show ST depressions in V₁ through V₃ and sometimes V₄ and V₅, often with tall R waves in V₁ through V₃ but without evidence of ST elevations (Fig. 55.5). This situation can be confused with anterior wall ischemia. Clues on the ECG to the diagnosis of isolated posterior wall MI include horizontal (rather than sloping) ST depressions with prominent R waves and tall upright T waves in leads V₁ through V₃. Occasionally, isolated posterior wall MIs are manifested as a nondiagnostic 12-lead ECG (Fig. 55.6, A), with small pathognomonic ST-segment elevations evident only when extended ECG leads are placed inferior to the tip of the left scapula (V₈) and in the left paraspinal line at the same level (V₉) (see Fig. 55.6, B). Posterior wall MIs are the result of occlusion of the posterior descending coronary artery or the posterior left ventricular branch.

**BOX 55.1 Differential Diagnosis of ST-Segment Elevation on Electrocardiography**

- ST-segment elevation myocardial infarction
- Pericarditis
- Benign early repolarization
- Left bundle branch block
- Left ventricular hypertrophy
- Left ventricular aneurysm
- Paced ventricular rhythms
- Prinzmetal angina
- Hyperkalemia
- Hypothermia with Osborne waves
- Intracranial hemorrhage
- Brugada syndrome
- Normal variant

---

**Fig. 55.2** A 12-lead electrocardiogram shows ST-segment elevation in leads V₁ through V₄, consistent with acute anteroseptal myocardial infarction. Note that rapid atrial fibrillation is also present.
Fig. 55.3  A, A 12-lead electrocardiogram shows ST elevation in leads II, III, and aVF, consistent with acute inferior myocardial infarction (MI). Note the reciprocal ST depressions in leads I and aVL. B, The right-sided precordial leads in a patient with acute inferior ST-segment elevation MI show ST-segment elevation in leads RV_2 and RV_5, consistent with concomitant right ventricular infarction.
Fig. 55.4  A 12-lead electrocardiogram shows ST elevation in leads II, III, and aVF with ST depressions and prominent R waves in V₁ through V₅, consistent with acute inferoposterior myocardial infarction. Note the sinus arrhythmia and premature ventricular beat.

Fig. 55.5  A 12-lead electrocardiogram shows ST depressions in leads V₁ through V₄ with prominent R waves in V₁ and V₂, consistent with isolated acute posterior myocardial infarction. Note that a complete heart block is also present.
Fig. 55.6  A, A 12-lead electrocardiogram (ECG) in a patient with chest pain is notable only for prominent R waves in the precordial leads with early R-wave progression. B, Extending the ECG to include right-sided and posterior leads demonstrates ST elevations in leads V₆ and V₉, consistent with isolated acute posterior myocardial infarction.
either of which can arise from the RCA (more commonly) or the left circumflex coronary artery.

Lateral wall MIs, characterized by ST-segment elevation in some or all of leads I, aVL, V₅, and V₆, may be associated with anterior MI as previously described or with inferior or posterior MI or may occur in isolation. This is because the lateral wall of the heart is variably supplied with blood by the LAD, the RCA, and the left circumflex artery. Isolated lateral wall MIs are most commonly associated with left circumflex artery occlusion; the ECG may show reciprocal ST depressions in leads II, III, and aVF (Fig. 55.7).

**Electrocardiographic Findings in Non–ST-Segment Elevation Acute Coronary Syndrome**

In the clinical setting of NSTEMI, the ECG may be normal or unchanged from baseline, although more commonly it will show ST-segment depressions, T-wave abnormalities, or both in the area of the ECG representing the area of ischemia or infarction in the heart (Fig. 55.8). As mentioned, ST-segment depressions in the precordial leads may also represent true posterior wall transmural infarction. In addition, ST depressions may also represent reciprocal changes, with STEMI occurring in another location; this is most commonly seen in the lateral leads in patients with an inferior STEMI or in the inferior leads in patients with a lateral STEMI (see Fig. 55.7). T-wave inversions are nonspecific findings, particularly when seen in isolation (without ST-segment depressions), but they do suggest ACS in the right clinical setting, especially when comparison with previous tracings shows that the findings are new. Note that T waves are normally inverted in leads aVR and V₁ and are variably inverted in leads III, aVF, aVL, and V₂.

One important subgroup of T-wave inversions occurs in the precordial leads. The changes may be symmetric deep T-wave inversions (Fig. 55.9, A) or more subtle biphasic T-wave changes. This pattern, referred to as Wellen syndrome, represents an unstable lesion in the LAD. Without prompt appropriate treatment, this lesion may lead to an anterior STEMI (see Fig. 55.9, B). The differential diagnosis of inverted T waves includes not only ACS but also left ventricular hypertrophy, LBBB, pericarditis, myocarditis, pulmonary embolism, Wolfe-Parkinson-White syndrome, ischemic or hemorrhagic stroke, hypokalemia, and a persistent juvenile pattern. These findings may also be normal variants. Occasionally, patients with chronically inverted T waves are found to have new upright T waves in the setting of chest pain or anginal equivalent. This finding, referred to as pseudonormalization of the T waves, is highly suggestive of ACS.

**CARDIAC BIOMARKERS**

Numerous cardiac biomarkers become elevated in the setting of myocardial cell death and are thus indicators of MI. The most sensitive and specific of these biomarkers at present are troponins, which are detectable in serum 4 to 10 hours after the onset of MI. Consequently, a single “negative” troponin value cannot be used to exclude MI. In addition to troponins, CK-MB and myoglobins are also useful and widely used. However, none of the cardiac biomarker measurements currently available represent an adequate test for unstable angina (without MI). For a complete discussion of cardiac biomarkers, see Chapter 54.

**OTHER TESTS**

Cardiac ultrasonography, nuclear imaging, and stress testing can be very important in confirming the diagnosis of ACS.
Fig. 55.8 A 12-lead electrocardiogram shows T-wave inversions in leads V₃ through V₆ and ST-segment depressions with T-wave inversions in leads II, III, and aVF, consistent with non-ST-segment elevation acute coronary syndrome.

Fig. 55.9 A, 12-lead electrocardiogram (ECG) in a woman with resolved chest pain. The deep symmetric precordial T-wave inversions represent Wellen syndrome. B, ECG from the same patient obtained 30 minutes later, now with recurrent chest pain. Note the anterior ST-segment elevation consistent with acute occlusion of the left anterior descending coronary artery.
or in suggesting an alternative cause of the symptoms. Most recently, contrast-enhanced multidetector computed tomography of the coronary arteries has been shown to have a role in the evaluation of patients with chest pain. These tests are discussed in detail in Chapter 56.

Findings on chest radiography are usually normal or unchanged from baseline in patients with ACS. However, the chest film can be useful to assess for other causes of chest pain, including pneumothorax, pneumonia, Boerhaave syndrome, and to a lesser degree, aortic dissection. In addition, chest radiography is valuable when ACS is complicated by congestive heart failure.

**TREATMENT**

**PREHOSPITAL MANAGEMENT**

Patients who activate the 911 system because of signs and symptoms associated with ACS should be assessed by paramedics, if available. Those exhibiting hemodynamic or respiratory compromise should be transported by an advanced life support unit. All patients should receive the following:

- Cardiac monitoring and, if possible, a prehospital 12-lead ECG
- Supplemental oxygen with pulse oximetry monitoring
- Intravenous access
- Aspirin, administered orally in the absence of known allergy
- Nitroglycerin administered sublingually in the absence of contraindications for ongoing chest pain

The prehospital staff should alert the receiving ED of the transport, and if evidence of STEMI is seen on the 12-lead ECG, this should be communicated to the ED staff specifically. In some communities, identification of STEMI in the prehospital setting will result in transport to a hospital capable of performing percutaneous coronary intervention (PCI), even if not the closest facility. Additionally, in some health care systems, prehospital identification of STEMI will allow immediate activation of cardiac catheterization laboratory personnel.

**HOSPITAL MANAGEMENT**

Figures 55.10 and 55.11 present treatment algorithms for STEMI and non–ST-segment acute coronary syndromes.

Treatment of ACS is time sensitive and aimed at improving myocardial tissue oxygen supply, reducing myocardial oxygen demand, protecting ischemic myocardium, restoring coronary blood flow, and preventing reocclusion of the artery. Specific therapy depends on where along the spectrum of disease the individual case lies. Generally, unless contraindicated, all patients receive aspirin, oxygen, beta-blocker therapy, nitrates, and antithrombin therapy. Use of other antiplatelet agents depends in part on the clinical situation, whereas revascularization strategies are used only in patients with STEMI.

**Platelet Inhibitors**

Aspirin remains the cornerstone of therapy across the spectrum of ACS. It is highly cost-effective and remains one of a few drugs with a mortality benefit in patients with ACS. In patients with STEMI, aspirin independently reduces mortality by approximately 23%. Aspirin is an antiplatelet agent that irreversibly inactivates platelet cyclooxygenase and also reduces the formation of prostacyclin by endothelial cells. It should be administered in the ED orally (chewed and swallowed) or rectally; the standard dose is 162 to 325 mg. The EP should take care to avoid using enteric-coated preparations in the acute treatment of ACS. The only true contraindication to aspirin in patients with ACS is a history of severe allergic reaction.

Clopidogrel is one of several currently available thienopyridines, a class of drugs that inhibits adenosine diphosphate–mediated platelet aggregation. These drugs are more potent platelet inhibitors than aspirin is. Ticlopidine, another drug in this class, is not generally used because of its slow onset of action and concerns about its adverse effects, which include neutropenia and, rarely, agranulocytosis. Prasugrel, a more potent thienopyridine recently approved for use in patients with ACS, may play an increasing important role in the future, but at present clopidogrel remains the most commonly used drug in this class. Clopidogrel has been shown to improve clinical outcomes in patients with non–ST-segment elevation ACS, particularly in those who undergo PCI. Clinical benefit is demonstrable within 24 hours of dosing, but it has been associated with a small increase in bleeding in those who undergo coronary artery bypass grafting (CABG) within 5 days of discontinuation of clopidogrel. The traditional loading dose of clopidogrel has been 300 mg orally, but 600 mg appears to be equally safe and may be more efficacious. Clopidogrel (300 to 600 mg orally) should be administered to all patients with ACS and documented aspirin allergy, as well as to those in whom a noninterventional approach is planned. Clopidogrel should also be administered to patients with non–ST-segment elevation ACS in whom emergency CABG is deemed unlikely; this may best be determined in consultation with a cardiologist. For patients with STEMI, clopidogrel, 300 mg, is indicated as an adjunct to fibrinolytic therapy. In patients with STEMI who will undergo PCI, it is reasonable to administer clopidogrel, 300 to 600 mg, in the ED, provided that transfer to the catheterization laboratory is not delayed as a result.

GP IIb/IIIa receptor blockers inhibit the final common pathway of platelet aggregation, namely, the cross-linking of two platelets by one strand of fibrinogen, a bivalent molecule with two binding sites specific for the GP IIb/IIIa receptor. As
Fig. 55.10  Assessment and treatment algorithm for ST-segment elevation myocardial infarction (STEMI). ACS, Acute coronary syndrome; ASA, acetylsalicylic acid; AV, atrioventricular; bpm, beats per minute; cath lab, catheterization laboratory; CCU, cardiac care unit; CHF, congestive heart failure; DTB, door-to-balloon time; ECG, electrocardiogram; EP, emergency physician; GP, glycoprotein; HR, heart rate; IV, intravenous/intravenous line; PCI, percutaneous coronary intervention; PO, orally; SBP, systolic blood pressure; UFH, unfractionated heparin.
**Fig. 55.11  Assessment and treatment algorithm for non-ST-segment elevation myocardial infarction.** ACS, Acute coronary syndrome; ASA, acetylsalicylic acid; CABG, coronary artery bypass grafting; CCU, cardiac care unit; CHF, congestive heart failure; ED, emergency department; ECG, electrocardiogram; GP, glycoprotein; IV, intravenous/intravenous line; LBBB, left bundle branch block; MI, myocardial infarction; STEMI, ST-segment elevation myocardial infarction; UFH, unfractionated heparin; VT, ventricular tachycardia.
already mentioned, activated platelets have 50,000 to 80,000 receptors on their cell surfaces, so in the absence of GP IIb/IIIa inhibitors, a complete platelet-fibrinogen web can develop rapidly. With proper dosing, however, platelet inhibition of greater than 85% can be attained. For this reason, GP IIb/IIIa inhibitors are the most potent platelet inhibitors currently available. Nonetheless, GP IIb/IIIa inhibitors have been shown to provide benefit only to the subgroup of patients with ACS who undergo PCI.

Three GP IIb/IIIa inhibitors are currently available in the United States: abciximab, eptifibatide, and tirofiban. Abciximab, the first agent developed, is a unique chimeric monoclonal antibody to the GP IIb/IIIa receptor. It binds to the receptor by steric hindrance in a noncompetitive fashion and has a long half-life, with antiplatelet effects persisting for 24 hours after discontinuation of infusion. Eptifibatide and tirofiban, referred to as “small-molecule GP IIb/IIIa inhibitors,” are derived from the poisonous venom of two different vipers and bind competitively to the receptor. As a result, both can prevent fibrinogen from initially binding to the GP IIb/IIIa receptor and also displace bound fibrinogen from the receptor. These drugs are cleared renally and have shorter half-lives, with their antiplatelet effects persisting for several hours after discontinuation of infusion.

GP IIb/IIIa inhibitors have been shown to provide benefit to patients with ACS treated by PCI. Some data also show benefit in troponin-positive patients who test positive for troponins, but not in patients who test negative or who are managed medically. Consequently, current recommendations for the use of this class of drugs are as follows:

- **Age greater than 70 years**
- **Signs of heart failure or heart block**
- **Heart rates lower than 60 or greater than 100 beats/min**
- **Systolic blood pressure less than 120 mm Hg**

Oral administration of beta-blockers may be preferable in the ED across the spectrum of ACS, but this remains to be determined in clinical trials. When intravenous use is deemed appropriate, several different agents are available, including metoprolol, atenolol, propranolol, and the ultrashort-acting esmolol. Metoprolol is most commonly used; it is administered in 5-mg increments by slow intravenous “push” up to a total of 15 mg. This can be followed by 25 to 50 mg given orally. Atenolol is the longest acting and thus is not generally the best choice for ED use.

Propranolol is not selective for β, -adrenergic receptor blockade but has been used effectively for many years. It can be administered intravenously in 1-mg increments titrated to the desired effect. Esmolol is ultrashort acting and must be administered by intravenous bolus followed by continuous infusion. Its ED utility is generally limited to patients in whom it is strongly suspected that beta-blockers will not be tolerated, such as those with chronic obstructive pulmonary disease or asthma.

**Beta-Blocking Agents**

Beta-blockers are an important first-line therapy for patients with ACS. These agents act by reducing the effects of catecholamines on the heart—they slow the heart rate, reduce myocardial contractility, and thereby lower myocardial demand for oxygen. They are also potent antiarrhythmic agents and lessen the likelihood of ventricular and atrial tachyarrhythmias. However, they have also been shown, when given intravenously to patients with STEMI, to increase risk for the development of cardiogenic shock, which counterbalances the salutary effects of beta-blockers and results in no overall mortality benefit. Thus beta-blockers should be administered intravenously with caution in the ED setting to patients with STEMI and specifically withheld, per the most recent American College of Cardiology and American Heart Association guidelines for STEMI, in the following settings:

- Supplemental oxygen should be administered to all patients with ACS, even if the initial oxygen saturation value is normal. This step is particularly important in patients treated with nitrates, which cause pulmonary arterial dilation and thereby impair the ability of the lung to autoregulate pulmonary blood flow. Treatment with oxygen reduces the areas of the lungs that are poorly oxygenated, thus giving less opportunity for shunting and resultant hypoxia.

**Anticoagulants**

Anticoagulant (or antithrombin) therapy is indicated for patients with ACS who have no contraindications to its use. These agents are particularly useful in patients with recurrent anginal symptoms, “positive” cardiac biomarker values, or ischemic changes on the ECG. Available agents include unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), fondaparinux, and direct thrombin inhibitors (DTIs). The heparins (UFH and LMWH) work by activating antithrombin III, which in turn inhibits thrombin and factor Xa. LMWH can also directly inhibit factor Xa. Fondaparinux inhibits factor Xa as its principal mechanism of anticoagulation, and DTIs, as their name suggests, act directly on
thrombin. The net result of therapy with all the drugs in this class is to prevent the conversion of fibrinogen to fibrin, thereby avoiding clot propagation. These drugs are contraindicated in patients with active bleeding. In addition, heparin and LMWH are contraindicated in patients with a known history of heparin-induced thrombocytopenia.

UFH has a synergistic salutary effect on ischemic outcomes when combined with aspirin in patients with ACS, particularly those with MI. Several LMWH preparations have shown efficacy in patients with ACS, but only enoxaparin has demonstrated an improvement over UFH. Therefore, enoxaparin is the LMWH of choice for the treatment of ACS. Current guidelines recommend the administration of UFH or enoxaparin to patients with ACS in conjunction with antiplatelet therapy. For non–ST-segment elevation ACS, enoxaparin (1 mg/kg given subcutaneously twice daily) is the preferred agent unless urgent CABG is planned. UFH is dosed as an intravenous bolus of 60 U/kg (maximum, 4000 units), followed by an infusion at 12 U/kg/hr (maximum, 1000 U/hr). UFH use must be monitored by serial prothrombin time determinations; such monitoring is not necessary in patients treated with enoxaparin. Either drug should be discontinued immediately in patients with evidence of bleeding or if thrombocytopenia develops.

Fondaparinux is a relative newcomer to the class of anticoagulant drugs. It is a pentasaccharide molecule that represents the terminal five saccharide moieties of heparin. Principally a factor Xa inhibitor, this agent is administered as a subcutaneous injection, with dose reductions required in patients with renal insufficiency. Fondaparinux already has indications for the treatment of venous thromboembolic disease, and data suggest that it is similar to enoxaparin in terms of safety and efficacy for the treatment of non–ST-segment elevation ACS. Current published guidelines recommend fondaparinux as an acceptable alternative to UFH or enoxaparin in patients with non–ST-segment elevation ACS. DTIs offer theoretic advantages over heparins in that they do not work through the intermediary antithrombin III to inhibit thrombin. Nevertheless, no convincing data have shown that DTIs provide clinical benefits over UFH or LMWH in ED patients with ACS. Because of this and their high cost, current ED use of the presently available DTIs—argatroban, hirudin, and bivalirudin—should be limited to patients with a history of heparin-induced thrombocytopenia.

**Morphine**

Morphine sulfate is an opioid analgesic that has fallen out of favor for the treatment of ACS. There is no compelling evidence in favor of its use, and reports suggest that its sedative effects are associated with an increased risk for respiratory compromise and aspiration. In addition, this agent may cause hypotension through arterial and venous dilation. Morphine has a small role in managing pain that is refractory to other antiischemic therapy and in reducing anxiety in patients in whom anxiety is a prominent feature. It may be delivered intravenously in 3- to 5-mg increments.

**Angiotensin-Converting Enzyme Inhibitors**

Angiotensin-converting enzyme (ACE) inhibitors have a limited role in the treatment of patients with ACS. This class of drugs, which causes afterload reduction, includes captopril, lisinopril, and enalapril. The principal acute adverse effect is hypotension. It is clear that ACE inhibitors are beneficial in the subset of patients with acute or preexisting left ventricular dysfunction. They are also useful as adjunctive therapy for patients with STEMI that is being treated with fibrinolytic therapy. However, no compelling data support the use of ACE inhibitors in the ED, and it is reasonable to defer their administration to the inpatient setting. If they are initiated in the ED, it is preferable to start with a low dose and increase it as tolerated by the blood pressure. Renal function should be monitored during the initial phases of therapy with ACE inhibitors.

**Revascularization Therapy**

Patients with STEMI who arrive at the ED within 12 to 24 hours of the onset of symptoms require urgent revascularization therapy. It can be accomplished mechanically with primary PCI or pharmacologically with fibrinolytic therapy. Although fibrinolytic therapy remains the most common strategy worldwide, use of primary PCI for STEMI has been growing rapidly in the United States and has been deemed a preferable approach in terms of safety and efficacy. If a primary PCI strategy is chosen, the IRA must be opened within 90 minutes of patient arrival at the health care system to achieve maximal efficacy. This interval includes time spent at the initial hospital if transfer to a PCI-capable facility is necessary. If the “door-to-balloon” target time of 90 minutes cannot be routinely achieved, a fibrinolytic strategy is preferable, particularly for patients who are seen early (within 3 hours of symptom onset).

For patients in cardiogenic shock or those with contraindications to fibrinolytic therapy, primary PCI should be performed as soon as possible. In addition, patients in whom fibrinolytic therapy fails, as evidenced by ongoing anginal symptoms and ST-segment elevations continuing an hour or more after therapy, should be referred for rescue PCI, which should be performed as soon as possible. Patients with STEMI who undergo primary PCI should also receive aspirin, clopidogrel, and UFH. It is reasonable to administer a GP IIb/IIIa inhibitor to these patients as well, and abciximab is the preferred agent in this setting. However, current evidence suggests that this decision can be safely deferred to the time of catheterization and PCI, which may allow the drug to be given more safely.

It is important to emphasize that none of these adjunctive therapies should delay transfer of the patient from the ED to the cardiac catheterization laboratory, which is the first priority. A number of validated strategies should be used to decrease door-to-balloon time. Those that specifically affect the ED are (1) empowering the EP to activate the entire cardiac catheterization laboratory team with a single phone call; (2) increasing, when possible, the capacity to obtain prehospital ECG tracings in patients with chest pain and activation of the catheterization laboratory team while the patient is still en route to the hospital; and (3) providing prompt feedback from a multidisciplinary quality improvement team to all clinical providers involved in care of the patient.

Fibrinolytic therapy remains an important treatment option for patients with STEMI, particularly those who go to community hospitals that do not have the capability of performing PCI. Rapid initiation of treatment is the standard of care, with a target goal “door-to-needle” time of less than 30 minutes. Fibrinolytic therapy is indicated for patients who have
symptoms consistent with ACS within 12 hours of symptom onset, meet ECG criteria (Box 55.2), and do not have an absolute contraindication to the therapy (Box 55.3). The presence of relative contraindications (Box 55.4) must be weighed against the risk of treatment delay if primary PCI is not readily available. Advanced age alone is not a contraindication, and although elderly patients treated with fibrinolytic therapy do have a higher incidence of hemorrhage, they also have a significantly higher mortality rate, which can be mitigated with therapy.

Several fibrinolytic agents are available. They include streptokinase, which is not fibrin specific and is administered as an intravenous infusion of 1.5 million units delivered over a 1-hour period, and tissue plasminogen activator (t-PA), which is fibrin specific and administered as a bolus followed by two separate weight-adjusted infusions. Considerable data suggest that the bolus-administered fibrinolytic agents reteplase (recombinant plasminogen activator [r-PA]) and tenecteplase are safer and easier to use than the infused fibrinolytic drugs and have equivalent clinical efficacy; cost are similar to that for t-PA. Both these newer agents are highly fibrin specific, and bolus administration lends itself to prehospital use if that is a consideration. r-PA is administered as a double bolus of 10 units intravenously at time 0 and again at 30 minutes; weight adjusting is not necessary. Tenecteplase is administered in a weight-tiered fashion as a single bolus of 30 to 50 mg based on known or estimated patient weight.

All patients with STEMI treated with fibrinolytic therapy should also receive aspirin and clopidogrel. Beta-blockers should be given with caution and perhaps should be limited in the ED setting to oral use in appropriate patients as discussed earlier. If a fibrin-specific agent is administered, UFH should be given in a bolus dose of 60 U/kg (maximum, 4000 units) and as an infusion of 12 U/kg/hr (maximum, 1000 U/hr). Enoxaparin can be safely and effectively substituted for UFH in patients with normal renal function who are younger than 75 years. If streptokinase is administered, either heparin preparation should be withheld.

Combination pharmacologic treatment of STEMI has attracted considerable interest. The most promising combination has been half-dose fibrinolytic therapy coupled with a GP IIb/IIIa inhibitor, which has been demonstrated to provide better angiographic outcomes in the IRA at 90 minutes. However, large-scale clinical trials have failed to show a mortality benefit of this combination, although they have suggested that it achieves reductions in the risk for recurrent MI and the need for rescue angioplasty. At present, combination therapy, because it is more expensive and cumbersome to administer, should be considered for use only in facilities whose remote locations make transfer of a patient for rescue PCI very difficult.

### BOX 55.2 Electrocardiographic Criteria for Fibrinolytic Therapy

ST-segment elevation of 0.1 mV or greater in two or more contiguous leads
Left bundle branch block not known to be old
ST-segment depressions and prominent R waves in leads V₁ through V₄

### BOX 55.3 Absolute Contraindications to Fibrinolytic Therapy

Previous history of intracranial hemorrhage
Known malignant intracranial neoplasm
Known cerebrovascular lesion (e.g., arteriovenous malformation)
Suspected aortic dissection
Active bleeding (excluding menses) or known bleeding diathesis
Significant closed-head or facial trauma within the previous 3 months
Ischemic stroke within the previous 3 months (except if within 3 hours)

### BOX 55.4 Relative Contraindications to Fibrinolytic Therapy

History of chronic, severe, poorly controlled hypertension
Uncontrolled hypertension at initial evaluation (systolic blood pressure higher than 180 mm Hg or diastolic blood pressure higher than 110 mm Hg)
Previous ischemic stroke more than 3 months earlier
Traumatic or prolonged (>10 minutes) cardiopulmonary resuscitation or major surgery within less than 3 weeks
Recent (within 2 to 4 weeks) internal bleeding
Noncompressible vascular punctures
Pregnancy
Active peptic ulcer
Current use of anticoagulants

### PRIORITY ACTIONS

1. Immediate 12-lead electrocardiogram for all patients with chest pain or anginal equivalent
2. Administration of aspirin to patients with acute coronary syndrome, the only contraindication being a true aspirin allergy
3. Prompt revascularization for patients with ST-segment elevation myocardial infarction (“door-to-needle” time of less than 30 minutes or “door-to-balloon” time of less than 90 minutes)
4. Early recognition and treatment of electrical and mechanical complications of acute coronary syndrome
5. Admission to a telemetry unit or coronary care unit for all patients with acute coronary syndrome
FOLLOW-UP AND NEXT STEPS IN CARE

All patients with ACS should be admitted to a hospital bed equipped with cardiac monitoring. In some institutions, patients with negative initial troponin test values and nondiagnostic ECG findings who are deemed to be at low risk for ACS may be admitted to ED- or cardiology-based chest pain observation units, where the remainder of the diagnostic and therapeutic evaluation may take place. In most hospitals, however, patients with suspected ACS are admitted as inpatients and generally to a cardiac intensive care unit. Cardiac consultation is indicated. Patients with STEMI who are managed with primary PCI go directly from the ED to the cardiac catheterization laboratory and thereafter to a cardiac intensive care unit.

Complications of ACS that are manifested acutely include congestive heart failure or cardiogenic shock (because of a large infarction or acute valvular incompetence) and rhythm disturbances (ventricular fibrillation, atrial fibrillation, and atrioventricular nodal block, among others). In patients with STEMI, particularly those with delayed revascularization and those who are revascularized with fibrinolytic therapy, myocardial rupture of the infarcted portion of the left ventricle can occur, generally in the period 1 to 5 days after infarction, and result in an acute ventricular septal defect with flash pulmonary edema or free wall rupture with tamponade. The most important longer-term complication is chronic congestive heart failure, development of which is dependent on several things, including the extent of the index MI and the speed and success of revascularization, as well as the degree of underlying heart disease and preexisting left ventricular dysfunction, ischemic in origin or otherwise. Ventricular tachyarrhythmia may also be a long-term complication of patients with ACS.

Cardiac Imaging and Stress Testing

Ryan T. Geers, John Deledda, and Andra L. Blomkalns

**KEY POINTS**

- Cardiac imaging and stress testing are key components of any comprehensive patient evaluation for possible acute coronary syndromes or coronary heart disease.
- Exercise or pharmacologic stress testing is used to risk-stratify patients and determine the presence of stress-induced ischemia.
- Rest myocardial perfusion imaging assesses for ischemia during symptoms at the time of evaluation, whereas stress testing evaluates for stress-induced (exercise or pharmacologic) ischemia.
- Rest myocardial perfusion imaging can be a useful tool for risk stratification and diagnosis in patients with active or recent chest discomfort (<2 hours).
- Echocardiography can be used to assess global cardiac function and may be performed with the patient at rest or with stress.
- Electron beam computed tomography is gaining momentum as an imaging technology that is potentially useful in the emergency department environment.
- Several chest pain unit protocols using various combinations of cardiac biomarkers, imaging modalities, stress testing, and time courses of evaluation have proved successful in many environments.
- Individual institutions and their emergency departments should develop their own custom protocols to best care for patients in that community given the resources available, personnel, and practice patterns.

**BACKGROUND AND SCOPE**

The diverse group of patients with symptoms of chest discomfort remains a significant challenge for the emergency physician (EP). High-risk patients with classic angina and young, low-risk patients with atypical symptoms represent only a fraction of those with chest discomfort seen in the everyday emergency department (ED) setting. Frequently, patients have one or two risk factors and some but not all of the classic ischemic symptoms, and the findings on an electrocardiogram (ECG) are nondiagnostic. These patients carry up to a 10% chance of significant cardiac disease and need appropriate risk stratification and diagnostic evaluation. As EPs, our goal is not to diagnose the condition of coronary heart disease but, rather, to stratify patients’ risk and identify those at risk for imminent cardiac ischemia and poor outcomes.

EPs use several methods and modalities to evaluate this very heterogenous patient group, each of which has benefits and limitations. Aside from a comprehensive history and physical examination, standard adjuncts include an ECG, serial cardiac biomarker measurements, and some choice of cardiac imaging. The ECG, though often considered the principal diagnostic tool in cardiac evaluation, is the most basic and rapid way to image the heart. Elevations in available cardiac biomarkers indicate the end result of ischemic myocardium and signify myocardial necrosis or cell death. Cardiac imaging indirectly reflects cardiac anatomy and tissue function with the goal of revealing occult cellular ischemia at risk for cell death. Cardiac imaging can be performed with the patient at rest or under physical or pharmacologic stress. Some of the factors to be considered for the appropriate choice of imaging modality include patient selection, exposure to radiation (Table 56.1), and availability of reagents, technology, and personnel to perform the study and interpret the results. The goal of this chapter is to familiarize the reader with common cardiac imaging modalities used in the ED for the evaluation of this difficult and high-risk population.

This chapter focuses on the most common and established cardiac imaging modalities of echocardiography and myocardial perfusion nuclear imaging. An example of how these modalities might be incorporated into an ED patient evaluation protocol is also presented. Finally, we briefly highlight the new and promising cardiac imaging capabilities of computed tomography (CT) and magnetic resonance imaging (MRI).

**ELECTROCARDIOGRAM**

An ECG should be obtained within 10 minutes of a patient’s arrival at the ED. Though often considered to be the most important diagnostic and prognostic tool available, ECGs rather primitively indicate only gross electrical derangements caused by dead or dying muscle tissue. Serial ECGs during progression or regression of a patient’s symptoms can be helpful, similar to procuring prior ECGs from a previous medical visit.

Common errors in reading ECGs include distinguishing between true posterior and right ventricular ischemia. A true
posterior infarction is suggested by marked ST depression, upright T waves, and tall R waves in the anterior leads (V1 to V3). This can be further confirmed by data acquired from posterior leads (V7 to V9) placed on the patient’s back. Because of the opposite direction of reading the ECG current, these leads (V7 to V9) will show ST-segment elevation with posterior ischemia. If unable to get posterior leads, flipping the regular ECG to view V1 to V3 upside down through the ECG paper can demonstrate what V7 to V9 would show. In comparison, the right ventricle lies on the anterior and inferior surface of the heart. This area is best reflected through right-sided leads in which the precordial leads are placed from the sternum to the right side of the patient’s chest (V1 to V6). ST-segment elevation in leads V2 to V4 indicates right ventricular involvement. Right ventricular involvement is commonly associated with inferior infarctions. These infarcts can be volume dependent, and such patients require careful use of nitrates and perhaps even small fluid boluses to maintain hemodynamic stability.

### CHEST ROENTGENOGRAM

Though not usually considered to be a cardiac imaging modality, the chest radiograph is an important diagnostic tool in the evaluation of patients with chest pain. Probably the most useful function of the chest radiograph lies in identifying or suggesting alternative diagnoses for the patient’s symptoms. Chest radiographs are safe and result in relatively low radiation exposure (0.02 millisievert) when compared with the cardiac-specific modalities (see Table 56.1). Pneumothorax or pneumonia can be identified on a chest radiograph. Mediastinal widening, apical capping of pleural fluid, tracheal deviation, or displacement of intimal calcium from the outer vessel wall may indicate aortic dissection. An enlarged cardiac silhouette may signify the presence of a pericardial effusion or, if seen together with pulmonary congestion, congestive heart failure. Pulmonary emboli may be accompanied by focal oligemia, wedge-based densities, or enlarged pulmonary arteries on chest radiographs. Every patient with chest discomfort should have a chest radiograph taken before additional evaluation.

### EXERCISE TREADMILL TESTING

Graded exercise testing is a popular method of cardiac stress testing in both the inpatient and outpatient settings. Many of the early ED accelerated diagnostic protocols used this test after initial risk stratification via cardiac biomarkers and the ECG.4,8 This was the beginning of chest pain unit protocols and the ability to appropriately risk-stratify ED patients with chest pain within 6 to 12 hours. Outcomes at 6 to 12 months have been found to be similar with very few adverse events between patients admitted to the hospital and those cared for in an ED chest pain unit setting. Although exercise treadmill testing has a lower positive predictive value (great proportion of false-positive results) than some other more contemporary myocardial perfusion imaging (MPI) modalities, its use still diminishes unnecessary admissions.

Selection criteria for exercise testing are more restrictive than those for other imaging modalities. Patients must be able to walk on a treadmill, and findings on the ECG should be normal or show no new changes. Agents such as dobutamine, dipyridamole, adenosine, or regadenoson can be used in lieu of exercise. Although exercise testing is slowly being supplanted by studies offering more detailed functional information, it is still a major tool in many centers (Fig. 56.1).

### TIPS AND TRICKS

Meet the patient’s expectations by explaining the process and time requirements for a comprehensive risk stratification protocol.

Even after a negative rest protocol result, be sure to emphasize to the patient the need to pursue further stress testing and risk factor modification.

Determine the patient’s ability to exercise before sending the patient for an exercise study. Many patients cannot exercise sufficiently for adequate results and ultimately need pharmacologically induced stress to maintain their heart rate in the appropriate range.

### ECHOCARDIOGRAPHY

#### REST ECHOCARDIOGRAM

Two-dimensional rest echocardiography enables real-time visualization of the anatomy and physiology of the heart and thereby provides an abundant amount of diagnostic information in patients seen in the ED. The procedure itself is safe, painless, and without radiation. In some patients with chest pain, a rest echocardiogram is a sensitive bedside test that can be an important tool in guiding diagnosis, therapeutic interventions, and final disposition of the patient.
Echocardiography is a comprehensive diagnostic tool for a number of conditions, including cardiac ischemia, acute pulmonary embolism, pericardial effusion, aortic dissection, pericarditis, hypertrophic cardiomyopathy, mitral valve prolapse, and aortic stenosis (Box 56.1).

Rest echocardiography has an important role in risk stratification of patients in the ED with potential myocardial ischemia. In a healthy heart, increases in heart rate and myocardial contractility are seen with cardiac stress. In patients with myocardial ischemia, segmental changes can be seen with rest echocardiography, including decreased wall thickness during stress, a decrease or no change in the ejection fraction, and abnormalities in segmental wall motion. Echocardiography can also be used to evaluate valvular heart disease, congenital heart defects, and pericardial disease.

**Box 56.1 Conditions Detected by Echocardiography**

- Cardiac ischemia
- Hypertrophic cardiomyopathy
- Aortic dissection
- Pericarditis
- Mitral valve prolapse
- Aortic stenosis
- Acute pulmonary embolism
- Pericardial effusion
fraction, and regional wall motion abnormalities. The diagnostic accuracy of rest echocardiography depends on several factors, including proximity in time to the patient’s symptoms, size of the myocardium affected, depth of the ischemic myocardial tissue, and limitations of the specific-generation technology being used. For these reasons, several studies have reported widely varying positive predictive (31% to 100%) and negative predictive (57% to 98%) values for detecting myocardial ischemia in the acute setting. Preliminary data indicate a potential ED use of echocardiographic contrast agents, which are absorbed by healthy myocardium and thereby more able to identify subtle regional wall motion abnormalities. Finally, EPs are continuing to gain prowess in bedside ultrasonography. However, at this point, focused cardiac ultrasound by EPs includes only a binary assessment (normal versus depressed) of global cardiac function.

STRESS ECHOCARDIOGRAM

Stress echocardiography provides additional diagnostic capability in detecting inducible wall motion abnormalities in patients who may have normal wall motion at rest. A stress echocardiogram can be performed immediately after the patient undergoes physical stress through the use of a treadmill or bike. Alternatively, if the patient is unable or unwilling to undergo exercise, pharmacologic stress with agents such as dobutamine can be used. Dobutamine is an adrenergic-stimulating agent that raises myocardial oxygen demand by increasing contractility, blood pressure, and heart rate. Dobutamine stress echocardiography (DSE) has performed well in providing excellent negative predictive value (NPV) for the diagnosis of obstructive coronary artery disease. The greatest diagnostic benefit of stress echocardiography is to provide prognostic information in patients with an intermediate pretest probability of having coronary artery disease. This may include patients with some combination of coronary risk factors (hypertension, smoking history, diabetes) and atypical angina, patients with typical angina without risk factors, and patients with abnormal baseline ECG findings. Studies have shown that these patients can be safely discharged from the ED with outpatient follow-up if the results of DSE are negative. In one ED study, DSE had NPVs of 98.8% for all cardiac events (hospital admission for angina and revascularization procedure) and 99.6% for hard cardiac events (cardiac death and nonfatal myocardial infarction). In several other studies, the NPV of DSE in patients undergoing ED chest pain protocols ranged from 91% to 96% for cardiac events at 6 months.

MYOCARDIAL PERFUSION IMAGING

MPI involves the injection of a radioisotope such as thallous chloride Tl 201 (thallium) or technetium Tc 99m radiopharmaceuticals and imaging of its uptake and diffusion through cardiac tissue. One important advantage of Tc 99m is that unlike Tl 201, it distributes to areas of highest myocardial perfusion and does not redistribute to other areas over time. This property allows the practitioner to inject the patient with the radionuclide agent during or proximate to the patient’s symptoms at rest and obtain the images several hours later.

MPI has gained wide acceptance for the diagnosis of myocardial ischemia in a variety of patient populations traditionally difficult to diagnose, such as women, asymptomatic diabetic patients, patients with existing ECG abnormalities such as left bundle branch block, and patients with severe renal disease. Gated single-photon emission computed tomography (SPECT) with an attenuation correction has made MPI even more valuable in the ED setting. With multihigh SPECT systems, imaging can often be completed in less than 10 minutes. Also with SPECT, inferior and posterior abnormalities and small areas of infarction can be identified, as well as the occluded blood vessels and the mass of infarcted and viable myocardium. Several landmark trials have shown a high NPV for MPI in the ED evaluation of chest discomfort. Although thallium imaging is more established, the diffusion kinetics of technetium Tc 99m makes it more desirable in the ED setting.
pulmonary embolism and aortic dissection ("triple rule out"). Both these modalities show promise in the risk stratification of low- to moderate-risk patients with chest pain.

Possible limitations include availability of this technology and radiologists or cardiologists to read these studies in real time. The previous requirement of lowering the patient’s heart rate grows less necessary with advanced multislice and source technologies. The results from ongoing studies will help determine the optimal role of CT in cardiac evaluation.

## MAGNETIC RESONANCE IMAGING

Current research continues to explore new and hopefully more effective imaging strategies for the evaluation of patients with chest discomfort in the ED. MRI can be used to determine both myocardial perfusion and regional wall motion abnormalities, including transient stunning after an ischemic event. Several studies have shown its utility in the diagnosis of acute coronary syndrome, and recent clinical trials have demonstrated its potential value in identifying atherosclerotic lesions and vulnerable plaque. We currently believe that limited availability and high cost preclude MRI from becoming a standard, acceptable modality until further studies demonstrate a decisive advantage over nuclear imaging or echocardiography.

## EXAMPLE OF A CHEST PAIN UNIT PROTOCOL THAT USES RISK STRATIFICATION AND CARDIAC IMAGING

Each institution should develop cardiac evaluation protocols based on the risk profile of its population and the availability of imaging modalities and in collaboration with emergency medicine, radiology, and cardiology physicians. Specific protocols and imaging modalities vary among locations and institutions. Figure 56.2 shows an example of a chest pain unit protocol at a large urban center.

---

### RED FLAGS

For nuclear imaging, the best results are obtained if the radiopharmaceutical is injected while the patient is experiencing symptoms or is undergoing exercise or pharmacologic stress.

Many protocols for stress testing preclude proximate caffeine ingestion. Make sure to note the patient’s prior caffeine intake and to have the patient avoid the inadvertent ingestion of any caffeine-containing product (regular or decaffeinated coffee, tea, soft drinks, and chocolate) during the initial evaluation phase.

Know the difference in the electrocardiographic findings of an inferior, right ventricular, and posterior infarction.

The pharmacy or nuclear medicine department regulates the supply of any nuclear imaging agent. If these agents are unused for a time, they expire and must be discarded. Additional preparation or acquisition of fresh agent may cause the work-up of an individual patient to be delayed.

Even if the cardiac imaging and evaluation results are negative, alternative diagnoses such as aortic dissection, peptic ulcer disease, and pulmonary embolism should be considered.

Patients should leave the emergency department with some idea about what may be causing their symptoms.

Two nuclear imaging studies, such as a technetium Tc 99m sestamibi scan and a ventilation-perfusion (V/Q) lung scan, cannot be performed within the same 24-hour period. If the differential diagnosis includes pulmonary embolism, alternative and complementary imaging modalities may have to be used.

Exercise and pharmacologic stress studies require that the patient’s heart rate rise to appropriate levels. The emergency physician should be cautious about starting beta-blocker therapy in patients who will undergo stress studies in the emergency department. Although beta-blockade is a standard treatment in patients with myocardial ischemia, it can hamper the physician’s ability to perform risk stratification for low-risk patients because it results in nondiagnostic stress evaluations.

---

### PATIENT TEACHING TIPS

Patients experiencing chest discomfort with or without the classic associated symptoms should call their emergency response system (i.e., 911) instead of driving to the nearest hospital.

To provide appropriate risk stratification, chest discomfort evaluation protocols may take several hours to finish.

A right-sided infarction and posterior infarction are separate clinical entities identified by separate and specific electrocardiographic findings.

Even after a negative rest imaging evaluation result, the patient should arrange for further risk assessment and stress imaging with a primary care physician or cardiologist.

Therapeutic lifestyle modifications and attention to modifiable cardiac risk factors should be part of any evaluation protocol.

The patient should keep copies of the imaging records, including a copy of the latest electrocardiogram, in a personal health file. These records can be tremendously useful to other physicians if further emergency cardiac evaluation is required.

---

CHAPTER 56  CARDIAC IMAGING AND STRESS TESTING
EVALUATION OF PATIENTS FOR ACUTE CORONARY SYNDROME

A – High risk for STEMI
B – High risk for UA/NSTEMI
C – Intermediate risk
D – Low risk
E – Very low risk

Fig. 56.2 Evaluation of patients for acute coronary syndrome (ACS). CAD, Coronary artery disease; CP, chest pain; CRI, chronic renal insufficiency; ECG, electrocardiogram; ED, emergency department; h/o, history of; LBBB, left bundle branch block; NSTEMI, non–ST-segment elevation; NSTEMI, non–ST-segment elevation myocardial infarction; PCP, primary care physician; PVD, peripheral vascular disease; STE, ST-segment elevation; STEMI, ST-segment elevation myocardial infarction; UA, unstable angina.

DEFINITIONS:

1 Typical angina:
   1) Substernal chest pain or discomfort that is 2) provoked by exertion or emotional stress and 3) relieved by rest and/or nitroglycerin

2 Cardiac marker timing: based on symptom onset; in cases of uncertainty assume symptom onset at ED arrival

3 ECG normal: no significant ST depression/T wave inversions, BBB, LVH with repolarization, conduction defect, digoxin effect

4 Anginal equivalent:
   • Any symptoms that the physician feels may represent ACS
   • Exertional dyspnea—most common anginal equivalent symptom

5 ACS:
   • STE-ACS—1 mm ST elevation in 2 leads
   • NSTEMI—positive cardiac biomarkers
   • Unstable angina—ischemia with negative biomarkers

6 New significant ECG changes:
   • ST $\Delta s \geq 0.5$ mm; resolve when asymptomatic
   • ST depression $\geq 1$ mm in 2 leads
   • T wave inversion $\geq 2$ mm in 2 leads

7 Regadenoson is preferred agent for chemical nuclear stress test. Technitium Tc-99m tetrofosmin is the preferred tracer.
A description of the patient’s symptoms should include onset, duration, severity, location, quality, context, associated symptoms, and modifying factors.

Documentation of a past family history of early coronary heart disease or acute coronary syndromes provides useful risk stratification information.

A social history of smoking or the use of cocaine should be documented.

Nuclear imaging documentation should include the patient’s last episode of chest discomfort, particularly whether a radiopharmaceutical was injected during the chest discomfort.

The clinician needs to justify an extended period of evaluation by documenting the need for further risk stratification and observation.

**SUMMARY**

Cardiac imaging is an important component in the evaluation of patients seen in the ED with chest discomfort. Astute clinicians should understand the benefits and limitations of each modality and should incorporate appropriate imaging into the framework of the institution, its resources, and its physician collaborators.

KEY POINTS

- Acute decompensated heart failure can be manifested as volume overload, acute diastolic dysfunction, and low cardiac output.
- Identifying and addressing the precipitants of the decompensation are as important as treating the decompensation itself.
- Biomarkers such as B-type natriuretic peptide and the inactive N-terminal fragment of B-type natriuretic peptide can assist in making the diagnosis, but it is important to understand the limitations of these tests.
- In patients with volume overload, diuretics remain the cornerstone of therapy.
- Not all patients with acute decompensated heart failure are significantly volume-overloaded; overaggressive diuresis risks hypotension and worsening renal function.
- Nitrates are first-line therapy for patients in whom an acute reduction in cardiac preload and afterload is desired.
- Inotropic therapy should not be routinely instituted unless the patient is in cardiogenic shock.
- For patients in respiratory distress, noninvasive support (continuous positive airway pressure or bilevel positive airway pressure) may reduce the need for endotracheal intubation.

Epidemiology

With the aging of the U.S. population and improved survival after myocardial infarction, the prevalence of heart failure is on the rise. At the same time, advances in medical therapy are allowing patients with heart failure to live longer. In 2008, 5.7 million Americans were estimated to have heart failure, with approximately 670,000 new cases diagnosed that year. Heart failure contributes to nearly 300,000 deaths per year, and costs associated with the treatment of heart failure exceed $30 billion annually. Heart failure accounts for nearly 1 million inpatient admissions per year and represents the primary reason for hospitalization in the growing elderly population. Approximately four of every five patients hospitalized for heart failure initially come to the emergency department (ED) for treatment.

Evidence-based literature for ED management of heart failure lags behind that of other emergency conditions, such as acute coronary syndrome and stroke. The number of large, randomized controlled clinical trials is small, and most practice guidelines, such as those from the Heart Failure Society of America and the European Society of Cardiology, rely heavily on consensus statements. A recent American Heart Association scientific statement highlighted the significant gaps in knowledge and the lack of evidence-based approaches to the management of heart failure in the ED. In contrast, data from the Acute Decompensated Heart Failure National Registry (ADHERE) and the Acute Heart Failure Global Survey of Standard Treatment (ALARM-HF) registry have provided important insight into the clinical characteristics and actual patterns of care of these patients.

In addition to the paucity of controlled clinical trial data, there remains confusion about terminology. Heart failure refers to the clinical syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood. Causes of chronic heart failure are numerous and diverse (Box 57.1), but in the United States the majority of cases arise as a consequence of coronary artery disease and long-standing hypertension. The term acute heart failure is reserved for the presence of acute signs and symptoms of heart failure in an individual without previously known structural or functional cardiac disease. Examples of acute heart failure are massive ST-segment elevation myocardial infarction, acute papillary muscle rupture, and fulminant myocarditis. Much more commonly, a patient comes to the ED with worsening symptoms of known chronic heart failure, in common parlance a “heart failure exacerbation.” The term acute decompensated heart failure (ADHF) has been adopted to describe this phenomenon, whereby a patient with an established diagnosis of heart failure...
Noncompliance with medications or dietary restrictions and myocardial ischemia are believed to be the most common causes of clinical cardiac decompensation. Other cardiovascular precipitants are arrhythmia (atrial fibrillation in particular), acute valvular dysfunction, and hypertensive crisis, but ADHF can also arise as a consequence of noncardiac conditions such as infections, anemia, alcohol withdrawal, uncontrolled diabetes, and thyroid disease.

**Presenting Signs and Symptoms**

The heterogeneity of the signs and symptoms in patients with ADHF reflects, to some extent, the relative contributions of volume overload, acute diastolic dysfunction, and low cardiac output. Volume overload, which usually occurs in the setting of medication noncompliance or dietary indiscretion (or both), is classically associated with gradually worsening congestive symptoms. Acute diastolic dysfunction can occur in the setting of myocardial ischemia, tachyarrhythmia, or uncontrolled hypertension and is typically manifested as flash pulmonary edema. Nearly half of all patients admitted to the hospital for ADHF have mild or no impairment in systolic function. Overt manifestations of low cardiac output (i.e., hypoperfusion) are not generally seen except in patients with advanced LV dysfunction.

Most patients with ADHF have some degree of dyspnea. However, ADHF can closely mimic many other cardiac, respiratory, and systemic diseases. Historical features such as a history of orthopnea, paroxysmal nocturnal dyspnea, or peripheral edema make the diagnosis of ADHF more likely. The most valuable single piece of historical information to elicit from patients is a previous history of heart failure, myocardial infarction, or coronary artery disease. For example, patients evaluated in the ED because of acute dyspnea are approximately six times more likely to have ADHF if they have previously experienced heart failure.

Older patients may lack the typical signs and symptoms of heart failure because they are obscured by the aging process itself or by the presence of coexisting medical conditions.
Nonspecific symptoms such as weakness, lethargy, fatigue, anorexia, and light-headedness may actually be manifestations of decreased cardiac output. Abdominal or epigastric discomfort can be a manifestation of low output or, more commonly, hepatic congestion.

Vital signs provide a sense of the severity of illness and can suggest etiologic factors for decompensation. Hyperthermia or hypothermia may indicate sepsis or thyroid disease. In the absence of rate-controlling pharmacologic agents, tachycardia is nearly universal in patients with decompensated heart failure.
failure. Bradycardia should raise concern for high-degree atrioventricular block, hyperkalemia, drug toxicity (digoxin, calcium channel blocker, beta-blocker), or severe hypoxia. Hypertension is commonly seen in patients with both systolic and diastolic dysfunction. Hypotension may represent baseline blood pressure (BP) in patients with end-stage cardiomyopathy but otherwise raises concern for shock, whether cardiogenic or otherwise.

The diagnostic utility of the physical examination has been well studied in the setting of chronic heart failure but less so for ADHF. It should be recognized that in ADHF, physical findings may be misleading because of the rapidly evolving clinical situation. Generally speaking, jugular venous distension, abdominojugular reflux, pedal edema, and an audible third heart sound are specific but insensitive indicators of heart failure, whereas the presence of pulmonary rales has only moderate specificity for heart failure (see Table 57.2).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis in patients with acute respiratory distress is broad and includes ADHF, asthma, chronic obstructive pulmonary disease (COPD), pneumonia, pulmonary embolism, and multiple systemic diseases, including sepsis.

Even before patients reach the hospital, ADHF is associated with significant morbidity and mortality, including malignant arrhythmias and prehospital cardiac arrest. With few exceptions, the safety and efficacy of prehospital interventions have been poorly studied. Prehospital therapy for decompensated heart failure should be undertaken with caution in light of the relatively high number of inaccurate diagnoses made in the field. In as many as 50% of patients with assumed heart- associated respiratory distress, a different condition is diagnosed once they arrive at the hospital. Despite these concerns, evidence suggests that prehospital therapy for presumed heart failure can prevent serious complications and improve survival, particularly for critically ill patients. For example, prehospital use of continuous positive airway pressure (CPAP) in patients with acute pulmonary edema may avert the need for endotracheal intubation.

Nitroglycerin appears to be the safest and most effective of the prehospital medications used for presumed pulmonary edema. The role of other medications for heart failure in the prehospital setting is less clear. Early administration of furosemide appears to have very little benefit and may result in short-term complications. Prehospital use of morphine sulfate for presumed pulmonary edema has been associated with a higher rate of endotracheal intubation, particularly in patients whose condition turns out to have been misdiagnosed in the field.

**EMERGENCY DEPARTMENT EVALUATION**

The approach to patients with ADHF begins with stabilization of respiratory and hemodynamic status and rapid exclusion or treatment of reversible life-threatening conditions. Clinical evaluation and empiric therapy begin simultaneously and consist of supplemental oxygen, cardiac monitoring, pulse oximetry, and intravenous access. Patients with clinical signs of exhaustion or hypoxia despite supplemental oxygen require respiratory support via either invasive or noninvasive means. Those with hypotension, obtundation, cool extremities, or other signs of poor perfusion should be presumed to be in or near cardiogenic shock and be managed accordingly. An electrocardiogram (ECG) should be obtained early to exclude ST-segment elevation myocardial infarction. Once the initial resuscitation is under way, further efforts should be made to establish the diagnosis of ADHF and identify an underlying cause of the acute decompensation.

**DIAGNOSTIC STUDIES**

**LABORATORY TESTS**

The majority of patients with complaints suggestive of ADHF will require laboratory testing. A complete blood count is useful for ruling out anemia as an alternative cause of the dyspnea or as a precipitant of ADHF. An elevated white blood cell count may suggest the presence of an infectious process, especially if bands are present; however, this finding has not been well studied in patients with suspected ADHF. Serum chemistry analysis is important for assessing renal function and overall fluid and electrolyte balance, particularly in patients already receiving diuretic therapy and likely to require additional diuresis.

**MARKERS OF CARDIAC ISCHEMIA**

Elevations in cardiac troponin levels may be found in up to one third of patients with ADHF and can identify patients with a worse short-term prognosis. In any individual case, it remains a clinical determination whether elevations in biomarkers (1) reflect an acute coronary syndrome (i.e., unstable plaque causing ischemia and myocardial cell death and leading to worsening heart failure) or (2) simply reflect the severity of the heart failure (i.e., myocardial cell death with or without underlying ischemia). Information from the history (e.g., onset of symptoms, comparison with previous episodes) and from the ECG may be helpful in this regard.

**B-TYPE NATRIURETIC PEPTIDE AND NT-PROBNP**

B-type natriuretic peptide (BNP) is a counterregulatory hormone produced by cardiac myocytes in response to increased end-diastolic pressure and volume, as occurs in the setting of heart failure. ProBNP is released into the circulation and cleaved into biologically active BNP and an inactive N-terminal fragment, NT-proBNP, which has a half-life three to six times that of BNP. Plasma levels of BNP and NT-proBNP correlate with the degree of LV overload, severity of clinical heart failure, and both short- and long-term cardiovascular mortality.

Plasma levels of BNP and NT-proBNP have been shown to be useful in distinguishing between cardiac and noncardiac causes of dyspnea. Acutely dyspneic patients with plasma BNP levels lower than 100 pg/mL or NT-proBNP levels lower than 300 pg/mL are very unlikely to have ADHF (90% to 99% sensitivity), whereas those with BNP levels higher than 500 pg/mL or NT-proBNP levels higher than 1000 pg/mL are very likely to have ADHF (87% to 95% specificity). Intermediate levels must be interpreted in the clinical context (Fig. 57.2).
Interpretation of BNP levels must take into account baseline LV dysfunction and other known or suspected conditions associated with left or right ventricular pressure overload that may result in elevations in BNP. Patients with advanced age or renal insufficiency tend to have higher BNP and NT-proBNP levels, whereas those with a high body mass index tend to have lower levels. Although BNP and NT-proBNP measurements retain discriminatory power in these subpopulations, the optimal cutoff points for diagnosing ADHF may vary. The duration of symptoms also plays a role; for example, in the setting of acute pulmonary edema, these levels may not yet be elevated.

In general, emergency physicians (EPs) are about 80% accurate in distinguishing between cardiac and noncardiac causes of dyspnea on clinical grounds. Supplementing clinical acumen with routine BNP or NT-proBNP measurement does increase diagnostic accuracy overall, but as demonstrated in the Breathing Not Properly Multinational Study, the improvement is rather marginal. For example, in clear-cut cases, very high or very low values are unlikely to have an effect on diagnosis, whereas in less clear-cut cases, intermediate results are more likely.

BNP and NT-proBNP levels also carry modest prognostic information. Although levels at admission correlate only modestly with short-term outcomes, discharge levels are strong independent predictors of death or readmission.

**ELECTROCARDIOGRAPHY**

The ECG is likely to be abnormal in patients with heart failure. Signs of preexisting conditions such as hypertrophy, myocardial infarction, or dilated cardiomyopathy may be present. Atrial fibrillation or other arrhythmias may be detected. A large proportion of heart failure exacerbations are accompanied by cardiac ischemia, which may be detectable on an ECG.

**CHEST RADIOGRAPHY**

A chest radiograph should be obtained in all patients with suspected ADHF to assess for pulmonary congestion and assist in the differential diagnosis of other lung diseases. Findings on chest radiographs in patients with ADHF include cardiomegaly, vascular redistribution (e.g., cephalization, fullness of the hilar vessels), interstitial edema, and pulmonary edema. Pleural effusions in patients with heart failure tend to be bilateral or localized to the right side. Although the presence of pulmonary congestion is associated with a very high likelihood of ADHF, it should be noted that as many as one in five patients with ADHF do not have evidence of congestion on chest radiographs. In individuals with underlying pulmonary emphysema, congestion may appear atypical or not at all, and patients with long-standing congestive heart failure (CHF) may have scant radiographic evidence of congestion because of well-developed pulmonary lymphatics. Cardiomegaly may be absent in patients with acute heart failure, particularly in those with preserved LV systolic function.

**CARDIAC ECHOCARDIOGRAPHY**

Echocardiography is considered the “gold standard” for assessing the status of LV function, distinguishing between systolic and diastolic failure, and identifying regional wall motion abnormalities. Perhaps more important in the ED setting, echocardiography can assist in diagnosing or excluding potentially reversible causes of acute cardiac decompensation, such as pericardial tamponade, massive pulmonary embolism, ruptured chordae tendineae, and ruptured ventricular septum. As a practical matter, emergency echocardiography is not generally required in most instances of ADHF, particularly if a patient has a history of heart failure and a clear precipitant for decompensation.

**PULMONARY ARTERY (SWAN-GANZ) CATHETERIZATION**

Invasive hemodynamic monitoring is not usually necessary for the diagnosis and management of ADHF, and its routine use is not recommended. In the absence of pulmonary disease or disproportionate right heart failure, clinical estimation or measurement of right atrial pressure usually correlates with
left-sided filling pressures. When compared with standard clinical management, hemodynamically guided therapy is not associated with improvement in short- or long-term outcome. Conversely, right heart catheterization remains a reasonable option in patients with cardiogenic shock or when a patient’s hemodynamic status is uncertain after careful clinical evaluation and initial therapy.

**OTHER DIAGNOSTIC MODALITIES**

Elevated end-tidal CO₂ concentrations and reduced peak expiratory flow rates are more commonly seen exacerbations of COPD than of ADHF. However, in neither case is a cutoff value available that can be used to accurately distinguish between cardiac and respiratory causes of dyspnea. Another noninvasive means proposed for aiding in the diagnosis of ADHF is impedance cardiography, in which real-time estimates of cardiac output and pulmonary capillary wedge pressure are derived via dynamic measurement of thoracic bioimpedance. Although the technology has been available for some time, data on the overall utility of this diagnostic tool in the ED setting are limited.

**TREATMENT**

**PRIORITIES OF TREATMENT**

All patients with ADHF who are in respiratory distress should receive supplemental oxygen and be positioned upright, if possible, to improve respiratory dynamics and maximize oxygen delivery to vital organs. Practice guidelines recommend the early application of monitors, such as pulse oximetry, noninvasive BP, and continuous cardiac monitoring, to provide early warning of further decompensation.

Although most patients in respiratory distress can be managed with supplemental oxygen and noninvasive ventilatory support (see the next section), the presence of agonal respirations or profoundly depressed mental status mandates endotracheal intubation. In general, airway management should be accomplished with rapid-sequence intubation because prolonged attempts at intubation risk worsening hypoxia, further cardiac decompensation, and cardiopulmonary arrest. Keeping the patient in an upright position as long as possible before intubation may assist in maximizing pre-oxygenation. Most induction agents (thiopental, fentanyl, and midazolam) are associated with a significant risk for hypotension in patients with ADHF, whereas induction with etomidate is generally considered safe.

**Noninvasive Respiratory Support**

For patients with respiratory distress in whom intubation is not immediately required, noninvasive respiratory support via CPAP or bilevel positive airway pressure (BiPAP) should be instituted (Fig. 57.3). Although the decision to initiate noninvasive respiratory support may depend on a variety of factors, the presumption is that the earlier therapy is instituted, the greater the likelihood of averting intubation. Success also depends on appropriate patient selection. Patients with unstable cardiac rhythms or cardiogenic shock are generally believed to not be candidates for a noninvasive approach. Likewise, in the setting of severe myocardial ischemia or infarction, full ventilatory support may be preferable to decrease myocardial oxygen demand.

CPAP improves lung mechanics by recruiting atelectatic alveoli, improving pulmonary compliance, and reducing the work of breathing. At the same time, particularly in patients with heart failure, CPAP improves hemodynamics by reducing preload and afterload, thereby enhancing LV performance. Pooled data from several randomized, controlled clinical trials suggest that the use of CPAP (at 5 to 10 mm Hg) in patients with respiratory distress caused by ADHF reduces the frequency of endotracheal intubation and may be associated with lower mortality.14

BiPAP adds to the physiologic advantages of CPAP during expiration by providing differential positive pressure during inspiration, thereby providing direct assistance with ventilation. However, at present, little evidence suggests an advantage of BiPAP over CPAP in patients with ADHF and pure hypoxemic respiratory failure.

In patients with progressive respiratory failure despite noninvasive support, endotracheal intubation and mechanical ventilation should be instituted.

**PHARMACOLOGIC THERAPY**

The twin objectives of pharmacologic therapy for ADHF are relief of pulmonary congestion and improvement in systemic tissue perfusion. Strategies to achieve these goals involve reducing preload and enhancing LV function while aiming to maintain or even improve myocardial oxygen balance (Table 57.3).

**Diuretics**

Diuretics constitute the mainstay of therapy for patients with volume overload. Although their use is widely recommended as initial therapy for most patients with ADHF, it should be noted that until very recently this practice had not been evaluated in any large, prospective trial. Evidence from in vitro and in vivo experiments suggests that the direct vascular effects of diuretics may also contribute to their mechanism of action. However, studies comparing the acute effects of diuretics and nitrates have tended to emphasize the more favorable overall hemodynamic effects of the latter group (see the next section).

Depending on a patient’s clinical condition and previous use of diuretics, an initial intravenous (IV) dose of

</tbody>
</table>

Furosemide, 20 to 200 mg, is typically administered. For patients already receiving diuretic therapy, a common strategy is to begin with the usual daily dose given as an IV bolus. A recently published multicenter, prospective, double-blind, randomized trial comparing a strategy of low-dose furosemide (equivalent to the patient’s previous oral dose) versus high-dose furosemide (2.5 times the previous oral dose) in 308 patients with ADHF found no significant differences in patients’ global assessment of symptoms or in the change in renal function over the first 72 hours. A high-dose strategy was associated with greater diuresis, but median length of hospital stay was not significantly different. In the same trial, patients randomized to bolus IV therapy (every 12 hours) or the same dose of furosemide delivered via continuous IV infusion had no significant difference in outcome.

It is important to recognize that not all patients with ADHF are substantially volume-overloaded. For example, patients with acute diastolic dysfunction may benefit more from redistribution of circulating volume (e.g., with a vasodilator) than from diuresis per se. The indiscriminate use of diuretics carries the risk for overdiuresis, with detrimental effects on systemic perfusion in general and renal function in particular.

Although not all patients with ADHF require bladder catheterization, monitoring of urinary output is important in any patient in whom diuresis is a chosen as a treatment strategy.

Nitroglycerin is effective in patients with poor skin perfusion. Although not all patients with ADHF require bladder catheterization, monitoring of urinary output is important in any patient in whom diuresis is a chosen as a treatment strategy.

Nitroglycerin is recommended for the treatment of ADHF, whether of ischemic or nonischemic origin. At low doses, nitroglycerin induces venodilation (preload reduction); at higher doses, nitroglycerin also causes arterial dilation (afterload reduction). Significantly, in patients with severe underlying LV dysfunction, afterload reduction appears to predominate over preload reduction, even with moderate doses of nitroglycerin.

Nitroglycerin have been shown to be both safe and effective for the treatment of ADHF, particularly in the context of acute pulmonary edema. When compared with placebo therapy in the Vasodilation in the Management of Acute Congestive Heart Failure (VMAC) trial, IV nitroglycerin resulted in better dyspnea scores, but the study was not powered to demonstrate differences in morbidity or mortality.

Single doses of sublingual nitroglycerin (0.4 mg) can be given repeatedly every 5 to 10 minutes to provide adequate BP. In the hospital setting, however, continuous IV administration of nitroglycerin is more convenient and allows titration to specific clinical or hemodynamic end points (typically starting at 10 to 20 mcg/min and ranging up to 200 mcg/min). The hemodynamic effects of transdermal nitroglycerin are comparable with those of IV nitroglycerin, but this route of administration is less amenable to titration and may be less effective in patients with poor skin perfusion.
The hypotension induced by standard nitrate therapy is generally mild and transient. Severe or persistent hypotension should raise suspicion for hypovolemia, stenotic valvular disease such as aortic stenosis, cardiac tamponade, right ventricular infarction, or recent use of sildenafil (Viagra). If these conditions are known or suspected, nitrates should be avoided or used with extreme caution. Nitrate therapy may not be particularly effective in patients with massive peripheral edema. In such cases, aggressive diuretic therapy is more likely to be of benefit.

Sodium nitroprusside is recommended for patients with marked systemic hypertension, severe mitral or aortic valvular regurgitation, or pulmonary edema not responsive to standard nitrate therapy. Nitroprusside profoundly dilates resistance vessels and thereby rapidly reduces BP and afterload. Typically, nitroprusside is started at a dose of 0.1 to 0.3 mcg/kg/min, and the dose is increased as needed to improve clinical and hemodynamic status while maintaining systolic BP above 90 mm Hg or mean arterial pressure above 65 mm Hg. In patients with renal insufficiency, long-term use of nitroprusside carries the potential for cyanide toxicity as metabolites of the agent accumulate.

**Nesiritide**

Nesiritide (recombinant BNP) is the only pharmacologic therapy for dyspnea associated with ADHF that has been approved by the U.S. Food and Drug Administration (FDA) in recent years. Like other natriuretic peptides, nesiritide has intrinsic vasodilatory as well as mild diuretic and natriuretic properties when administered in supraphysiologic doses (2-mcg/kg bolus, followed by continuous infusion at 0.01 mcg/kg/hr).

A number of trials have shown nesiritide to be more effective than placebo in improving hemodynamic parameters in patients with ADHF, but it is less clear what, if any, clinically important outcomes are improved. In the VMAC trial, pulmonary capillary wedge pressure was lower in patients receiving nesiritide than in those receiving nitroglycerin, but dyspnea scores at 3 and 24 hours were not significantly different between the two randomized groups. Studies have yet to show differences in more durable outcomes, such as of length of hospital stay and hospital costs.

Pooled data from several trials have suggested an association between nesiritide and adverse events, specifically, worsening renal function and death. In contrast, in a more recent multicenter trial, nesiritide demonstrated no excess adverse effects on either renal function or mortality in patients with ADHF. However, in this same trial, nesiritide failed to meet primary efficacy end points with respect to improvement in dyspnea or 30-day outcomes when compared with placebo.

**Angiotensin-Converting Enzyme Inhibitors**

The beneficial effects of angiotensin-converting enzyme (ACE) inhibitors in patients with chronic heart failure have been appreciated for more than 2 decades. Though not formally recommended by consensus guidelines for the treatment of ADHF, small studies have demonstrated their safety and efficacy as treatment of ADHF.

ACE inhibitors are contraindicated in the context of pregnancy, hyperkalemia, or a history of ACE inhibitor–induced angioedema. Unlike nitrates, most ACE inhibitors have a relatively prolonged duration of action, thus making their dosage less easily titratable.

**Inotropic Therapy**

Outside the setting of cardiogenic shock (see later), inotropic therapy is not recommended for the routine management of ADHF. Although short-term inotropic therapy may improve hemodynamic performance and acute symptoms, the impact on outcomes is considerably less salutary. One of the largest randomized placebo-controlled trials ever conducted in patients with ADHF, the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF), showed no difference in mortality or readmission rate in patients receiving inotropic therapy but significantly higher rates of adverse events, particularly sustained hypotension and new atrial arrhythmias.

Nevertheless, in patients with severe signs and symptoms of low-output failure or no response to standard therapy, short-term treatment with inotropic agents may be considered. The goals of therapy must be considered carefully in the context of the patient’s risk for arrhythmia.

Digoxin has a very limited role in the ED management of heart failure. The inotropic effects of digoxin are modest and unpredictable, and they are delayed for at least 90 minutes after intravenous loading.

**Morphine**

Morphine, one of the oldest drugs still in use for the treatment of ADHF, remains an important adjunct for treating the anxiety and discomfort associated with pulmonary edema. The predominant hemodynamic effects of morphine appear to be mediated through the central nervous system. Morphine can be administered safely to most patients at low IV doses (2 to 4 mg); however, because of its sedative properties and potential to depress respirations, caution should be exercised in administering morphine to patients with chronic pulmonary insufficiency or suspected acidosis. Although a number of retrospective studies have shown an association between administration of morphine to patients with ADHF and higher rates of adverse events, it is not clear that this link is causative.

**Investigational Drugs**

Over the past decade, a number of newer drugs ranging from various receptor antagonists to calcium sensitizers and novel neuropeptides have been investigated for the treatment of ADHF. Despite early promise with many of these agents, none have been shown in a prospective, placebo-controlled, randomized clinical trial to meet a primary clinical end point with respect to the treatment of ADHF.

In the EVEREST trial, tolvaptan, a vasopressin antagonist, improved short-term signs and symptoms in patients hospitalized with ADHF and receiving standard therapy, but this was not a primary end point of the long-term study. Tolvaptan was, however, approved by the FDA in 2009 for the treatment of hyponatremia associated with heart failure, among other hypervolemic states.

Relaxin, a natural peptide structurally similar to insulin that has unique vasodilator properties, is currently in phase III trials as a potential treatment option for ADHF.
**Beta-Blockers**
Long-term beta-blocker therapy affords an important survival benefit for patients with systolic heart failure. In contrast, administration of beta-blockers to patients with acute systolic dysfunction has been associated with life-threatening clinical deterioration. For this reason, institution of beta-blocker therapy is not recommended in the setting of ADHF, and long-term beta-blocker therapy is generally administered cautiously or at a reduced dose.

**ULTRAFILTRATION**
A novel approach to the problem of volume overload involves ultrafiltration of peripheral blood to remove excess fluid and electrolytes. Though typically reserved for patients with significant renal failure or volume overload unresponsive to diuretics, evidence from the Ultrafiltration vs IV Diuretics for Patients Hospitalized for Acute Decompensated CHF (UNLOAD) trial demonstrated that as an alternative to diuretic therapy, ultrafiltration results in greater fluid loss and lower rates of rehospitalization. In the ED, a major limitation of this approach is the feasibility of securing the necessary equipment and intravenous access.

**SPECIAL CIRCUMSTANCES**

**CARDIOGENIC SHOCK**
Heart failure with cardiogenic shock can be the initial manifestation of acute ST-segment elevation myocardial infarction. Although mortality remains high in this setting, referral for emergency cardiac catheterization and revascularization is of proven benefit. Noncardiac causes of shock, such as hypovolemia, sepsis, poisoning, and massive pulmonary embolism, must also be considered.

Aside from addressing reversible causes of shock, the overarching goal in treating patients with cardiogenic shock should be to restore and maintain perfusion of vital organs. Patients who are initially seen in shock with normal BP or only mild hypotension often have a favorable response to dobutamine (starting at 2 to 3 mcg/kg/min). When compared with dopamine, dobutamine is associated with a lower incidence of arrhythmias, less peripheral vasoconstriction, and more consistent reduction in LV filling pressure for a comparable rise in cardiac output. Dopamine is required for patients who have severe hypotension (systolic BP of approximately 70 to 80 mm Hg) in the presence of volume overload or after bolus administration of saline. At moderate doses (4 to 5 mcg/kg/min), dopamine improves cardiac output without causing excessive systemic vasoconstriction. If the patient can be stabilized with dopamine, dobutamine can then be added and the dose of dopamine lowered, with the goal of reducing myocardial oxygen demand. In extreme cases, norepinephrine can be added to increase systolic pressure to acceptable levels (≥80 mm Hg). However, because of the adverse effects on renal and mesenteric perfusion, use of high-dose dopamine or norepinephrine should be considered only as a temporizing measure until definitive therapy can be substituted.

It is important for the EP to distinguish patients with acute cardiogenic shock from those with low BP or other signs of systemic hypoperfusion in the setting of preexisting severe or end-stage systolic heart failure. Assessment and treatment of these patients can be extremely challenging, and optimal management may require the involvement of a heart failure specialist. Attempts to aggressively treat these patients can lead to rapid decompensation. Frequently, the key to management is identifying the cause of the decompensation.

**ATRIAL FIBRILLATION**
Atrial fibrillation is seen in approximately one third of patients with ADHF. Although loss of synchronized atrial contractions is of minimal hemodynamic significance in patients with normal ventricular function, in those who have abnormal LV systolic or diastolic function, loss of the atrial kick can have profound consequences. This is particularly evident when atrial fibrillation is accompanied by a rapid ventricular response, thereby reducing filling time.

When assessing a patient with rapid atrial fibrillation and ADHF, it is often difficult to attribute cause and effect. New-onset rapid atrial fibrillation may be the precipitant of ADHF, but more commonly, rapid atrial fibrillation is a response to worsening heart failure (e.g., via neurohormonal activation). This distinction can sometimes be difficult to make clinically, but regardless, attention must be paid, to some degree, to managing both conditions.

Management of atrial fibrillation in the context of ADHF should focus on treating the underlying precipitants of decompensation (e.g. volume overload) while also controlling the ventricular rate. However, caution should be exercised in the use of a beta-blocker or calcium channel blocker for rate control because of the potential negative inotropic effects. Digoxin, diltiazem, and amiodarone are considered acceptable agents for rate control, even in patients with LV systolic dysfunction. Cardioversion, whether electrical or chemical, is a reasonable treatment alternative for truly unstable atrial fibrillation, but sinus rhythm may not be achieved or maintained if the underlying heart failure is not addressed.

**RENAL DYSFUNCTION**
In part because of common preconditions such as diabetes and hypertension and in part because of the effects of diuretics and low cardiac output on renal function, heart failure and renal insufficiency frequently coexist. Approximately 1 in 5 patients with ADHF have creatinine levels higher than 2.0 mg/dL. In patients with ADHF, preexisting renal insufficiency is associated with greater morbidity and mortality, and worsening of renal function over the course of treatment is associated with poorer outcomes.

In patients undergoing hemodialysis, heart failure is the most common reason for ED visits. Not surprisingly, ADHF is frequently a result of volume overload between dialysis treatments. Although hemodialysis is the obvious treatment of choice for these patients, it may not always be immediately available, and supplemental oxygen, CPAP, and nitrates are generally effective in stabilizing patients until hemodialysis can be performed.

**FOLLOW-UP AND NEXT STEPS IN CARE**
The vast majority of patients with ADHF evaluated in the ED are admitted to the hospital. Discharge from the ED without
adequate treatment may be associated with recurrent visits and short-term morbidity and mortality. ADHF is often a dynamic entity: one patient may appear dramatically ill at initial evaluation but respond rapidly to treatment, whereas another patient may experience serious complications after a period of apparent stability. For any individual patient, identifying and addressing the precipitant of the decompensation is critical to making the correct disposition.

The Heart Failure Society of America has established criteria for discharging patients with heart failure from the ED (Box 57.3). However, these guidelines have not been prospectively studied. It should be noted that previously published criteria from the U.S. Agency for Health Care Policy and Research failed to account for more than 30% of 30-day mortality. Thus, although published guidelines can assist with triage, the significant rate of morbidity mandates that clinical judgment be incorporated into the decision-making process.

For patients with ADHF admitted to the hospital, inpatient mortality is approximately 4%, and the median length of stay exceeds 4 days. In those admitted with advanced stages of heart failure, inpatient mortality approaches 10%. Clinical correlates of major complications or death during hospitalization include hypotension; tachypnea; ECG abnormalities; hyponatremia; renal insufficiency; elevations in troponin, BNP, and NT-proBNP; and poor initial diuresis. However, even patients without any of these risk factors have measurable rates of in-hospital morbidity and mortality. A risk stratification tool derived from the ADHERE registry has been developed to help clinicians determine the risk for mortality in patients with ADHF (Fig. 57.4).

For a patient discharged home from the ED, consultation with the patient’s primary care physician or cardiologist is important. For example, it is likely that the patient’s outpatient medication regimen will require adjustment to prevent a return to the ED. In some studies, intensive outpatient

**Box 57.3 Heart Failure Society of America Recommendations for Discharge of Emergency Department Patients with Heart Failure**

**Admission is recommended for:**
- Severe acute decompensated heart failure:
  - Hypotension
  - Worsening renal function
  - Altered mental status
  - Dyspnea at rest
  - Arrhythmia with hemodynamic compromise, including new-onset atrial fibrillation
  - Acute coronary syndrome

**Admission should be considered for:**
- Worsening congestion (pulmonary or systemic)
- Significant electrolyte disturbance
- Associated comorbid conditions:
  - Pneumonia
  - Pulmonary embolism
  - Diabetic ketoacidosis
  - Transient ischemic attack, cerebrovascular accident
  - New-onset heart failure

---

follow-up has been shown to be successful in preventing recurrent ED visits and hospitalizations.

**OBSERVATION UNITS**

ED observation units have been advanced as a safe and cost-effective means of treating a subset of ADHF patients, thereby avoiding the need for hospital admission. Admission to an observation unit allows the ED physician to assess a patient’s response to diuretic (or other) therapy over time. Although interest in this field is growing, no randomized studies have been performed to date to substantiate the use of such units.26

Bradyarrhythmias

Sarah A. Stahmer

EXTRANSLIC CAUSES

Clues to an extrinsic cause of a bradyarrhythmia are a history of a new cardioactive medication, conditions that activate vagal tone, and extreme electrolyte imbalances, specifically potassium (Table 58.1). The associated rhythms are typically those that are due to dysfunction of the sinus or atrioventricular (AV) node:

- Sinus bradycardia, arrest (Figs. 58.1 to 58.3)
- Type I second-degree AV nodal block (Fig. 58.4)
- Third-degree heart block (see Fig. 58.6)

INTRINSIC CAUSES

Certain conditions result in failure of elements of the conduction system because of aging, ischemia or infarction, surgical trauma, or infiltration (Table 58.2). The latter cause encompasses a large group of conditions that include infectious and rheumatologic diseases.3-5 The associated rhythms are typically those that indicate failure of one element of the conduction system rather than failure to generate a rhythm:

- Second-degree AV block (either type I or type II) (Fig. 58-5; also see Fig. 58.4)
- Third-degree heart block (Fig. 58.6)
- Associated fascicular or bundle branch blocks (see Fig. 58.5)

RELATIVE BRADYCARDIA

Relative bradycardia is the presence of a heart rate that is inappropriately slow for the clinical findings. Though often caused by coexisting beta-blocker therapy or age-related blunting of sinus node automaticity, it is also a diagnostic feature of a number of infectious disorders. Relative bradycardia is most useful in differentiating infectious diseases that resemble each other; for example, legionnaires’ disease from Mycoplasma pneumonia and psittacosis or Q fever from tularemia pneumonia.3

PRESENTING SIGNS AND SYMPTOMS

Cardiac output is dependent on the patient’s stroke volume and heart rate. Bradyarrhythmias are symptomatic only to the extent that they affect cardiac output, which is a product of

- Look at the patient first and then the heart rhythm. A “slow heart rate” is relative to the patient’s age, clinical condition, and comorbid conditions.
- Determine whether the cause is extrinsic or intrinsic to the conduction system.
- Assess the functionality of the key elements of the conduction system: sinoatrial and atrioventricular nodes and the infranodal conduction system.
- Know the vascular supply of the conduction system to determine the significance of bradyarrhythmias and conduction blocks in the setting of acute myocardial infarction.
- Identify risk for failure of the conduction system and the “backup”; for example, a stable escape rhythm, atropine, or a pacemaker.

EPIDEMIOLOGY

Bradyarrhythmias are the result of either (1) extrinsic factors slowing the normally functioning sinus node and conduction pathways or (2) failure of the sinus node and conduction pathways because of intrinsic causes of degeneration of the conduction system.

PATHOPHYSIOLOGY

Bradycardia is a frequent finding in trained athletes, in whom heart rates lower than 40 beats/min are often observed at rest.3 Bradycardias of clinical significance increase in frequency with age and in the setting of illnesses or medications affecting the heart and its conduction system.
the heart rate and stroke volume. In the setting of a normal stroke volume, heart rates as low as 20 to 30 beats/min can sustain a reasonable cardiac output. A heart rate of 40 beats/min may be physiologically normal for some individuals, whereas a rate of 60 beats/min may be inadequate for patients with conditions that compromise stroke volume, such as cardiomyopathies, bleeding, or sepsis.

Symptoms of low cardiac output are due to hypoperfusion of vital organs and muscle tissue. Mild reductions in cardiac output usually cause exertional fatigue and dyspnea. Greater reductions in cardiac output can produce signs and symptoms of cerebral ischemia, congestive heart failure, mesenteric ischemia, and renal insufficiency. Complete heart block with slow escape rhythms or bradycardia in the setting of profound reductions in stroke volume can manifest as syncope, pulmonary edema, and cardiogenic shock.

Alternatively, a profound bradycardia that does not result in hemodynamic compromise does not need to be treated but should be considered an important diagnostic clue. The classic example is a patient with intracranial hemorrhage and Cushing reflex, which will be manifested as hypertension and often profound bradycardia. In this case the bradycardia is a sign of elevated intracranial pressure, and treatment should focus on reducing it.

### Differential Diagnosis and Medical Decision Making

The key to diagnosis and treatment is accurate interpretation of the 12-lead electrocardiogram (ECG). Though not a comprehensive review of all bradyarrhythmic rhythms, the following are those commonly encountered.

### Sinus Bradycardia

For the diagnosis of sinus bradycardia, P waves must be present at a heart rate of less than 60 beats/min. The morphology of the P wave must be consistent with a sinus beat (upright in leads I and II), and each P wave must be followed by a QRS complex with a fixed PR interval.

### Sick Sinus Syndrome

Sick sinus syndrome consists of a group of diseases characterized by dysfunction of the sinus node that can have a variety of appearances on an ECG. The most common ECG finding is severe, inappropriate sinus bradycardia. Another frequently encountered form is sinus arrest with a prolonged period (>2.5 seconds) and no atrial activity. The final form of sick sinus syndrome is tachycardia-bradycardia.

---

**Fig. 58.1** Rhythm strip of a patient with a bradycardia that is due to a hypervagal response. The initial portion of the strip shows a sinus rhythm with progressive slowing to the point of sinus arrest. In addition, there is progressive prolongation of the PR interval, which indicates that atrioventricular node conduction is affected as well. This finding suggests that the cause is “external” and affecting both the sinoatrial and atrioventricular nodes and not intrinsic disease of either node.
**Fig. 58.2** Sinus bradycardia with a ventricular response rate of 59 beats/min. There is a P wave for every QRS complex and normal PR intervals.

**Fig. 58.3** Sick sinus syndrome. This syndrome has many variants, but all have the common feature of abrupt dysfunction of the sinus node. This electrocardiogram shows a normal sinus rhythm with abrupt absence of P waves.

**Fig. 58.4** Mobitz type I second-degree heart block. This is sinus rhythm at 70 beats/min with a slower ventricular rate because of a progressive delay in atrioventricular (AV) nodal conduction and, finally, a dropped beat. Note that the PR interval after the dropped beat is shorter than the PR interval just before the dropped beat. The hallmark feature of this type of second-degree AV block is the presence of a normal sinus rhythm with a progressive delay in AV nodal conduction.

MI, Myocardial infarction.

Fig. 58.5  Mobitz type II second-degree atrioventricular block. Careful review of this electrocardiogram shows a sinus rhythm with a left anterior fascicular block and a right bundle branch block. Importantly, there is evidence of an anterior wall infarct with ST-segment elevation in the anterior leads. This demonstrates a significant complication of anterior wall infarcts involving the septum, with necrosis of the right bundle branch and left anterior fascicle and intermittent failure of the left bundle branch.

Fig. 58.6  Complete atrioventricular block. This electrocardiogram shows an underlying sinus rhythm that is regular at approximately 80 to 90 beats/min. The ventricular escape rhythm is slow and regular with no apparent relationship between the P waves and the QRS complexes.
syndrome, which is characterized by alternating periods of severe bradycardia interrupted by paroxysms of supraventricular tachycardia, usually atrial fibrillation.

SECOND-DEGREE HEART BLOCK
These heart blocks will be manifested as bradycardia only if the sinus rhythm is slow or a significant percentage of the sinus beats are not conducted.9

Type I Second-Degree Atrioventricular Block
The key ECG feature of a Mobitz type I second-degree AV block (i.e., a Wenckebach block) is progressive lengthening of the PR interval leading to a dropped QRS complex. The PR interval of the first-conducted QRS complex after a nonconducted beat has the shortest or a relatively normal PR interval. These blocks are usually indicative of a medication effect, AV node disease, or ischemia, but the rhythm is rarely the source of the instability10 (Fig. 58.7; also see Fig. 58.4).

Type II Second-Degree Atrioventricular Conduction Block
Diagnosis of a Mobitz type II heart block is determined by the presence of an intact sinus pacemaker with intermittent failure of conductance to the ventricles. This is due to failure of either the bundle of His or one of the Purkinje fibers. This rhythm is indicative of significant disease of the infranodal conducting system and is likely to progress to a complete heart block. These blocks are often due to myocardial ischemia and are symptomatic (see Fig. 58.5).

THIRD-DEGREE ATRIOVENTRICULAR BLOCK
This rhythm should be considered first in a patient with bradyarrhythmia because it is always clinically significant, often hemodynamically compromising, and unstable (Fig. 58.8; also see Fig. 58.6). The ventricular rate is typically very slow, but the actual rate varies according to the inherent rate of the escape rhythm. In this rhythm there is evidence of independent activity because of no connection between the atria and ventricles. It is important to “march out” the P waves to see if they are regular because some are most likely buried within or are part of the QRS complex or T wave. It should be apparent that there is no fixed relationship between the P waves and the QRS complexes. The QRS complexes can be narrow or wide, depending on the location of the escape pacemaker. Junctional escape pacemakers are faster (50 to 60 beats/min), narrow, and relatively stable in comparison with a ventricular escape rhythm, which is slow (30 to 40 beats/min), wide, and unstable. Often, the most helpful feature of the ECG for this rhythm is that the QRS complexes should be absolutely regular. This is a rhythm initiated by a slower pacemaker exhibiting spontaneous automaticity that has “escaped” the influence of the overriding sinus rhythm. Escape rhythms fire automatically at their inherent rate and are regular. Any irregularity in the escape rhythm suggests a high-grade incomplete AV block or an inherently unstable escape rhythm.

BRADYCARDIA ASSOCIATED WITH A WIDE QRS COMPLEX
Bradycardia associated with a “new” widening of the QRS complex suggests a cause that results in diffuse slowing of depolarization and conduction and that usually implicates agents that block the fast sodium channels or their ability to repolarize. This bradycardia is typically seen in patients with poisoning from agents such as tricyclic antidepressants, in patients with hypothermia, or in those with hyperkalemia (Figs. 58.9 and Fig. 58.10).

Fig. 58.7 This electrocardiogram shows diffuse ST elevations involving both the inferior and anterior walls. The ventricular rate is irregular, which indicates that the rhythm is originating from the sinus node and is not an escape rhythm. Though not the typical pattern of a Mobitz type I second-degree heart block, the progressive lengthening of the PR intervals suggests that the block is occurring at the level of the atrioventricular node. This conduction disturbance may be responsive to atropine.
**Fig. 58.8** Acute myocardial infarction and third-degree atrioventricular block. The sinus rhythm is regular and slow. The lead II rhythm strip shows that there is no fixed relationship between the P waves and the QRS complex. The ventricular response is also regular and narrow, thus suggesting a junctional escape rhythm in the setting of an inferior wall myocardial infarction. The block is at the level of the atrioventricular node and may be responsive to atropine.

**Fig. 58.9** Hyperkalemia. This electrocardiogram (ECG) is from a 52-year-old man who complained of generalized weakness in the previous week. The ECG shows a very slow rhythm that is regular and has a wide QRS complex. No obvious P waves are present, and the morphology of the QRS complexes is not typical for a right or left bundle branch block. The differential diagnosis includes sinus arrest with an escape rhythm and electrolyte abnormalities. After treatment with intravenous calcium gluconate, insulin, and 5% dextrose in water, the heart returned to a normal sinus rhythm with a narrow QRS complex. The patient’s serum potassium value was found to be 7.1 mEq/L.

Type I second-degree heart block: Sinus rhythm with progressive PR prolongation and a nonconducted beat. The PR interval of the conducted beat following the blocked beat is the shortest interval in the sequence. The QRS complex is usually narrow.

Type II second-degree heart block: Normal sinus rhythm with fixed PR intervals. Random sinus beats are not conducted to the ventricle. The QRS complex is often wide.

Third-degree heart block: Sinus rhythm with P waves visible. The ventricular response rate is regular but slower than the atrial rate with no visible relationship between the P waves and QRS complexes. The QRS rate and width are dependent on the site of the escape rhythm. The junctional escape rate is 40 to 60 beats/min and the QRS complex is narrow. The ventricular escape rhythm is 30 to 45 beats/min and the QRS complex is wide.

Bradycardia is relative. When cardiac stroke volume is normal, perfusion (e.g., blood pressure and cerebral perfusion) can be perfectly adequate even with ventricular response rates in the 30s. When a patient is symptomatic with a bradycardia, it is often multifactorial in etiology and attention must be paid to optimizing the stroke volume with fluids, reversing the ischemia, or adding inotropic agents in addition to increasing the heart rate.

Bradycardia not associated with hypotension or signs of hypoperfusion may be normal.

Bradycardia not associated with hypotension or signs of hypoperfusion may be an important clue to potentially serious conditions such as elevated intracranial pressure, electrolyte disturbances, or cardiac toxicity from medications.

Bradycardias associated with a wide QRS complex should be reviewed carefully for the presence of a complete heart block or medication or electrolyte effects.

Bradycardia or conduction disturbances in the setting of acute myocardial infarction should be looked for and recognized as a potential clinically significant complication.

**Fig. 58.10** Electrocardiogram showing sinus bradycardia with Osborn waves distorting the QRS complexes. These are classic findings in patients with clinically significant hypothermia. Treatment consists of rewarming and monitoring the patient’s condition via telemetry.

**TREATMENT**

**PREHOSPITAL CARE**

Respiratory disorders and myocardial ischemia are often associated with bradycardia, and prehospital care should focus on optimizing oxygenation, ventilation, and blood pressure and on relieving ischemia if present. Treatment of bradycardia is indicated only for patients who have a bradycardia that is inappropriate for the clinical condition and the patient is symptomatic (Fig. 58.11).

1. Optimize oxygenation (supplemental oxygen) and/or ventilation (continuous positive airway pressure) if needed.
2. Establish intravenous access.
3. Place the patient on telemetry and obtain a 12-lead ECG if possible.
4. If the absolute ventricular response rate is the probable cause of the hemodynamic instability, the following interventions may be helpful:
   a. Atropine, 0.5 mg intravenously (IV) up to 3 mg, may be effective for sinus bradycardia, Mobitz type I second-degree AV block, and third-degree heart block.
   b. Glucagon, 1 mg IV, may be effective for beta-blocker and calcium channel blocker toxicity.
   c. Calcium gluconate, 10 mL of a 10% solution IV, may be effective for calcium channel blocker toxicity or hyperkalemia.

HOSPITAL CARE

On arrival at the hospital, a slow heart rate will be readily identified while obtaining triage vital signs. The patient should be assessed rapidly for conditions that would cause the bradycardia through a screening examination for respiratory distress, medication toxicities, or myocardial ischemia. Once identified, disease-specific treatment plans will usually treat the bradycardia as well. Mainstays of management include the following:
1. Optimize oxygenation and ventilation.
2. Establish intravenous access and administer bolus intravenous fluid if the patient is hypotensive without signs of congestive heart failure.
3. Obtain a 12-lead ECG and rhythm strip.
4. Interventions:
   a. The patient remains hemodynamically compromised by the heart rate:
      - Sinus bradycardia, type I second-degree heart block, third-degree heart block:
        - Atropine, 0.5 mg IV up to 3 mg; atropine dosing should be aimed at obtaining the lowest heart rate that will optimize perfusion. In the setting of myocardial ischemia, the clinician must carefully balance the priority of maintaining perfusion to vital organs without exacerbating the myocardial ischemia.
        - Glucagon, 1 mg IV, may be effective for beta-blocker and calcium channel blocker toxicity.
      - Calcium gluconate, 10 mL of a 10% solution IV, may be effective for calcium channel blocker toxicity or hyperkalemia.
      - Temporary pacemaker.
   b. Type II second-degree heart block, third-degree heart block (particularly with a wide QRS complex):
      - Atropine is unlikely to work when the location of the block is in infranodal tissue (e.g., the bundle of His or more distal conduction system) because the blockade is less likely to be reversed with anticholinergic medication. These blocks are preferably treated with temporary pacing or β-adrenergic support as temporizing measures while the patient is being prepared for permanent transvenous pacing.
      - Dopamine hydrochloride can be effective in hypotensive, bradycardic patients and can be titrated to more selectively target the heart rate or vasosconstriction. Initial dosing in an unstable patient should start at 2 to 5 mcg/kg/min and be titrated to optimize blood pressure.
      - Epinephrine is a catecholamine with α and β activity and may increase the heart rate and support the blood pressure. The infusion can be initiated at 2 to 10 mcg/min and titrated to patient response. Use of vasoconstrictors requires that the recipient be assessed for adequate intravascular volume and volume status supported as needed.
      - Temporary pacing.
   b. The patient is not hemodynamically compromised by the heart rate:
      - Sinus bradycardia, type I second-degree heart block:
        - Treat the underlying cause—myocardial infarction (MI), myocardial ischemia.
        - Discontinue the offending medication.
        - Optimize electrolytes and volume status.
      - Type II second-degree heart block, third-degree heart block:
        - Temporary pacemaker.
        - Cardiology consultation.
• Treat the underlying cause—MI, myocardial ischemia.
• Optimize electrolytes and volume status.

CONSULTATION
Cardiology consultation is recommended for bradyarrhythmias that require pacemaker support and those that are due to failure of the infranodal conduction system or occur in the context of MI. Temporary cardiac pacing (TCP) can be an effective bridge to permanent pacemaker placement. The limited data on the effectiveness of TCP in patients with symptomatic bradycardia show that it is comparable with atropine and dopamine when hospital survival is used as an outcome.11 Its clinical utility is limited by the fact that it is poorly tolerated by awake patients and capture may be unreliable over time. It is reasonable to initiate TCP in unstable patients who do not respond to oxygen, fluids, and pharmacologic interventions as noted earlier. The decision regarding implantation of a pacemaker depends on the underlying cause and the likelihood that the AV block will be permanent. Many conditions affecting the conduction system will predictably resolve, such as electrolyte abnormalities, medication effects, hypothermia, and inferior wall MI, and will require at most TCP. Conversely, pacemaker implantation is indicated, even without hemodynamic instability, for conditions that are likely to progress and place the patient at risk for failure of the conduction system.12,13

Bradycardias caused by intrinsic disease of the myocardial conduction system are typically type II second-degree heart blocks and third-degree heart block and will usually require permanent pacemaker placement. Type I second-degree heart blocks rarely result in clinically significant bradycardia, but pacemaker therapy is warranted in patients who progress to complete heart block that does not respond to pharmacologic interventions.

MI is associated with significant bradyarrhythmia 25% to 30% of the time.14 The underlying mechanism is either direct ischemic injury to the sinus node, AV node, or conduction system or exaggerated vagally mediated reflexes. The bradyarrhythmias and conduction blocks associated with inferoposterior infarcts are commonly due to vagal reflexes, are responsive to atropine, and are usually transient5,10 (see Figs. 58.7 and 58.8). Sinus bradycardia and AV nodal blockade in the context of an inferior wall MI have been attributed to a higher density of cardiac afferent receptors in the inferoposterior portions of the heart. For hemodynamically compromising bradycardias, atropine is an excellent initial therapy, particularly in the first 6 hours. Doses should be administered in 0.5-mg increments with a maximum dose of 0.04 mg/kg or 3 mg. Doses lower than 0.5 mg should be avoided because of the risk for a paradox bradycardic response. When atropine is ineffective, transcutaneous or transvenous pacing is indicated. It is uncommon for type I second-degree and third-degree heart block to be the primary cause of hypotension in a patient with acute MI. Hypotension is usually due to poor stroke volume from the MI, and therapeutic effort should focus on restoring blood flow to the myocardium.

The conduction blocks associated with anterior infarcts typically involve the septum and the bundle branches that run through it. These blocks are not responsive to atropine and generally require permanent pacemaker support. Conduction blocks are typically those that are due to type II second-degree heart block or third-degree heart block. The anterior circulation perfuses the septum containing the His-Purkinje fibers. Ischemia and infarction of the septum may result in failure of one of the fascicles to conduct, usually the right bundle and left anterior fascicle, which lie in the anterior portion of the septum. Fascicular failure alone does not result in bradycardia as long as there is one functioning fascicle in sinus rhythm. Bradycardia may occur with either intermittent failure of the one remaining fascicle to conduct or failure of the bundle of His, which results in a type II second-degree heart block or third-degree heart block. Treatment is placement of a permanent pacemaker.12,13

PRIORITY ACTIONS
1. Determine whether the patient is hemodynamically compromised by the bradyarrhythmia. If the patient is hypertensive, determine whether it is due to the absolute heart rate or associated conditions that will cause a relative bradycardia to be symptomatic, such as volume loss or left ventricular dysfunction.
2. Establish intravenous access.
3. If it is determined that the absolute ventricular response rate is inappropriate for the clinical condition, the following interventions may be helpful:
   • Atropine, 0.5 mg intravenously up to 3 mg, may be effective for sinus bradycardia, Mobitz type I second-degree heart block (particularly in the setting of inferior wall myocardial infarction)
   • Glucagon, 1 mg intravenously, for beta-blocker and calcium channel blocker toxicity
   • Calcium gluconate, 10 mL of a 10% solution intravenously, for calcium channel blocker toxicity

4. Indications for temporary transcutaneous pacemaker placement include the following:
   • Symptomatic bradycardia unresponsive to pharmacologic therapy
   • Mobitz type II second-degree block
   • Third-degree heart block

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

ADMISSION
Admission for patients with bradycardia is dependent on the underlying cause, the extent to which the bradycardia is clinically significant, and whether interventions require in-hospital monitoring, treatment, or both.

PROGNOSIS
The prognosis varies with the cause of the bradyarrhythmia. Bradyarrhythmias secondary to extrinsic causes are reactive and usually recoverable once the offending agent or condition is removed. Intrinsic causes often suggest disease of the cardiac conduction system and require permanent pacing. Rarely is a recognized bradyarrhythmia a primary cause of death.
Bradyarrhythmias are a symptom, not a disease. Frequently, the underlying cause is clearly identified, and documentation is fairly simple—for example, the patient is experiencing effects of a new blood pressure medication. When the cause is less clear, the documentation must clearly include or exclude variables that must be considered in the work-up and treatment:

- Determine the clinical significance of the bradycardia. Did the patient pass out or complain of chest pain, exertional fatigue, or dyspnea? Precipitating factors such as nausea, head turning, tight ties, and new medications are important clues to the underlying cause.
- Does the patient have underlying cardiac disease, specifically left ventricular dysfunction, that would contribute to a bradycardia being symptomatic?
- The medical history should include a detailed medication list and recent dosing history.
- The physical examination may provide clues to the cause of the bradycardia:
  - Lethargy and hypertension—elevated intracranial pressure
  - Dialysis catheter or shunt—hyperkalemia
  - Obesity and sonorous breathing—sleep apnea
- The electrocardiogram and frequently multiple electrocardiograms, particularly when the patient reports symptoms, often specify the diagnosis.

### PATIENT TEACHING TIPS

Patients have the ability to exacerbate symptoms in specific conditions that cause bradycardia and thus should be given guidelines to avoid doing so if possible. These generally fall into the category of extrinsic causes of bradycardia:

- Patients with cough, micturition, and bradycardia or syncope should be advised to seek treatment to minimize triggers and to have access to support rails. Patients should lie down when lightheaded and should call 911 for persistent or particularly severe symptoms.
- Patients with carotid sinus hypersensitivity should avoid wearing tight ties and buttoned collars.
- Patients with documented sensitivity to medications that affect the sinus node or the atrioventricular node (or both) should report this fact when being prescribed any new medications.

### PITFALLS

Bradycardia is readily identified because of the heart rate being an essential component of triage and monitoring of vital signs. The diagnosis is dependent on accurate interpretation of the ECG in the context of the patient’s overall medical findings. Treatment “failures” are often due to the clinician’s focus on the bradycardia without consideration of the underlying cause. When the bradycardia is not causing hemodynamic instability, it does not need to be “treated” but remains an important clue to underlying conditions, such as medication effects, elevated intracranial pressure, pulmonary hypertension, or cardiac ischemia.

Heart rhythms with rapid rates, or tachydysrhythmias, have a range of causes and associated incidences, morbidities, and mortality. Atrial fibrillation (AF) occurs in up to 5% of people older than 65 years. Conversely, sustained ventricular tachycardia (VT) is rare and accounts for less than 0.1% of emergency department (ED) visits. Morbidity ranges from temporary lightheadedness to syncope and deterioration, ventricular fibrillation (VF), or embolization and subsequent permanent disability as a result of ischemic stroke. Mortality from atrial tachydysrhythmias is generally low. Mortality from VT is approximately 5%, and that from VF ranges from 80% to greater than 90%, depending on the clinical circumstances. A particular exception to the low mortality associated with atrial tachydysrhythmias is AF or flutter with rapid ventricular excitation via a bypass tract, such as in Wolff-Parkinson-White (WPW) syndrome.

Tachycardia is defined as a rhythm with at least three consecutive heartbeats occurring at a rate higher than 100 beats/min. The primary mechanisms for tachycardia are enhanced automaticity, reentry, and triggered beats. Sometimes a combination of these mechanisms is required for both initiation and maintenance of the tachydysrhythmia. The normal progression of depolarization in the heart begins with the sinus node, followed by the atria, the atrioventricular (AV) node, the His-Purkinje system, and the ventricles. Sinus and AV nodal tissue depolarization is mediated primarily by calcium channels, and depolarization of the other cardiac tissue is mediated by sodium channels. Repolarization is mediated predominantly by potassium channels. Automaticity is a characteristic of cardiac tissue wherein the cells depolarize at a periodic rate according to the tissue subtype. Sinus node tissue normally has the fastest intrinsic rate, and thus the sinus node serves as the pacemaker for the heart. Abnormal tachycardia occurs when other foci or circuits supersede the sinus node rate.

Enhanced automaticity occurs when the normal periodicity of cells is accelerated. Such acceleration may be either a normal physiologic response to increased sympathetic tone or fever or a pathologic response to an overdose of a medication such as digoxin or theophylline, a stimulant such as an amphetamine or cocaine, or other extrinsic factors. An automatic tachycardia occurs when an ectopic focus of tissue develops a heart rate greater than the sinus rate and paces the heart.

Reentry refers to a microscopic or macroscopic circular pattern of myocardial depolarization. A wave of excitation passes around the circuit and depolarizes the cells until it arrives at the beginning, and the process repeats itself. Reentry can occur if the circuit is sufficiently long or there is a slow-conducting portion that allows enough time for cells to have recovered from their refractory period before the wave of excitation returns (Fig. 59.1). The reentrant rhythm becomes the cardiac pacemaker if it is sufficiently fast to outpace the sinus node.

Tachydysrhythmias can also be initiated or triggered by small depolarizing ion movements that occur during or after normal cellular repolarization. These ion movements are termed early afterdepolarizations (EADs) and delayed afterdepolarizations (DADs), respectively. They can trigger a new wave of excitation in myocardial tissue before the normal sequence of depolarization from the sinus node. Unlike early beats secondary to enhanced automaticity, these beats have a
close correlation with the preceding beat and its repolarization phase. Some tachydysrhythmias use multiple dysrhythmic mechanisms (e.g., an EAD may initiate a reentrant tachycardia).

**PRESENTING SIGNS AND SYMPTOMS**

Patients with tachydysrhythmias may be entirely asymptomatic or may have a range of symptoms. They may be light-headed or may experience palpitations, chest discomfort, shortness of breath, transient syncope, or sudden death.

Signs of tachycardia include a rapid pulse and heart sounds. An irregularly irregular pulse is often detectable in patients with AF and atrial flutter or atrial tachycardia (AT) with variable AV conduction. VT may be associated with retrograde ventriculoatrial conduction, or AV dissociation may be present. In patients with VT and AV dissociation, signs of dissociation may be difficult to discern but can include variable intensity of the first heart sound and arterial or jugular venous pulsations. Tachycardia can lead to congestive heart failure (CHF) secondary to inadequate diastolic filling, myocardial ischemia, or other mechanisms. If CHF occurs, typical signs such as jugular venous distention, rales on pulmonary auscultation, and dependent edema may be present.

The primary findings to assess in the diagnosis of a patient with a tachycardiac electrocardiogram (ECG) are as follows:

- The presence, periodicity, and morphology of the P waves
- The relationship of the P waves, if any, to the QRS complexes
- The morphology of the QRS complexes and other waves as compared with a previous tracing if available
- The response of the ECG tracing to vagal maneuvers and other therapies such as adenosine infusion may also uncover the underlying rhythm diagnosis.

**DIFFERENTIAL DIAGNOSIS**

A variety of noncardiologic conditions can cause syncope and other symptoms that may suggest a tachydysrhythmia. Inadequate oxygenation of vital organs may be due to anemia, hemoglobin malfunction, or respiratory failure. Metabolic derangements include hypoglycemia, hyperthyroidism, dehydration, and fever. A hyperadrenal state secondary to acute excitement or agitation or, uncommonly, to pheochromocytoma can lead to sinus tachycardia. Neurologic events such as a seizure or cerebrovascular accident can cause tachycardia and altered consciousness, which can be confused with a primary tachydysrhythmia. Intoxication with stimulants and anticholinergics can manifest similarly. Overdose with prescription medications such as antihypertensive agents can result in tachycardia and hypotension.

Primarily nondysrhythmic cardiopulmonary conditions should also be considered in the differential diagnosis. Valvular disease, particularly that involving the aortic site, can lead to tachycardia, chest discomfort, or inadequate cardiac output with subsequent syncope. Hypertrophic obstructive cardiomyopathy can cause inadequate cardiac output if the subaortic hypertrophy obstructs cardiac outflow, and pulmonary embolism can lead to pulmonary vasospasm and obstruction to flow. Conditions leading to tamponade, such as pericardial effusion and tension pneumothorax, compromise cardiac output by impairing diastolic filling.

**TREATMENT**

The primary emergency therapies for tachydysrhythmias include medications to slow electrical conduction or to increase the cellular refractory period in the AV node or other groups of cardiac cells (Table 59.1). The goal of therapy is to terminate and suppress the abnormal rhythm or to slow the response in the remainder of the heart. Electrical therapy, including synchronized cardioversion and defibrillation, is used in potentially or frankly unstable patients. Electrical therapy has the advantages of high efficacy and safety, but shocks are painful and do not prevent recurrence of the tachydysrhythmia. Patients with higher heart rates, regardless of the underlying rhythm, have compromised diastolic filling and

cardiac output. These patients should be treated more aggressively with early electrical therapy. The emergency physician (EP) should understand and use antidysrhythmic medications but should minimize the use of multiple agents in a single patient. Use of multiple drugs increases the likelihood of drug interactions and compromised cardiac output.

See Table 59.1, Select Tachydyssrhythmia Medications, online at www.expertconsult.com

SPECIFIC TACHYCARDIAS

Primary tachycardiac conditions can be divided most simply into those of supraventricular and ventricular origin (Box 59.1; Fig. 59.2; see also Fig. 59.1). Supraventricular tachycardia (SVT) must involve tissue above the ventricles but may also involve ventricular tissue in a tachycardiac circuit, whereas VT involves only ventricular tissue below the AV node. The remainder of the chapter deals with the diagnosis and treatment of specific tachycardiac conditions.

**BOX 59.1 Major Tachydyssrhythmias**

**Supraventricular Tachycardias**
- Irregular
  - Atrial fibrillation
  - Multifocal atrial tachycardia
- Regular
  - Sinus tachycardia
  - Atrial flutter
  - Atrial tachycardia
  - Atrioventricular tachycardia
  - Atrioventricular nodal reentrant tachycardia
  - Junctional tachycardia

**Ventricular Tachycardias**
- Monomorphic ventricular tachycardia
- Polymorphic ventricular tachycardia
- Normal QT interval
- Prolonged QT interval
- Acquired versus congenital

**Fig. 59.2**  
SUPRAVENTRICULAR TACHYCARDIAS

Irregular Supraventricular Tachycardias

ATRIAL FIBRILLATION  The most common cause of an irregularly irregular heartbeat, AF is particularly common in the elderly, as well as in patients with preexisting cardiopulmonary disease. The mechanism is rapid, quasiperiodic, chaotic reentry within the atria. Consequently, the AV node is bombarded with atrial excitation waves at a high irregular rate. Conduction of signals through the AV node is limited by the refractory period of the nodal tissue. The AV node cannot conduct until the cells have recovered from depolarization and are ready to fire again. This determines the rate of the irregular ventricular response to AF.

The clinician can usually diagnose AF at the bedside by feeling the pulse, listening to the heart sounds, and observing a single-lead cardiac monitor. The ECG may show fine or coarse irregular undulations of the baseline and an absence of regular P waves. The QRS complex is usually normal; however, if the ventricular response is rapid, the QRS complex may be transiently widened because of intermittent aberrant conduction through the His-Purkinje system (Fig. 59.3). This finding, termed the Ashman phenomenon, can occur when areas of the His-Purkinje tissue have a longer refractory period than the AV node does. Such bursts of wide QRS complex tachycardia can be confused with nonsustained VT, but on close inspection the rhythm remains irregularly irregular.

The most common treatment issue for patients with AF in the emergency setting is control of the ventricular rate. Depending on the function of the patient’s AV node, the ventricular rate may range up to approximately 150 beats/min in adults. Ventricular rates this fast allow insufficient time for diastolic filling of the heart. The rate can be slowed with a variety of agents that act to lengthen the refractory period of the AV nodal tissue, such as calcium channel blockers, magnesium, digoxin, and amiodarone. Digoxin is less useful in the emergency setting because it takes a few hours to work, but the other agents must be used carefully because they can decrease blood pressure to varying degrees. The calcium channel blocker diltiazem usually provides excellent rate control with minimal loss of blood pressure. Beta-blockers may cause a greater loss of blood pressure and must be used with caution in patients with CHF or pulmonary disease. There is no indication for the administration of adenosine in patients with AF. The diagnosis should be made on the basis of findings from the history, physical examination, and ECG. Furthermore, adenosine, which only transiently blocks AV nodal conduction, would have no lasting therapeutic benefit.

If a patient with AF has a rapid ventricular response and associated hypotension, emergency cardioversion should be considered. It is unusual for AF alone to cause hypotension, so the possibility of additional causative conditions that can be corrected, such as dehydration, occult hemorrhage, and the metabolic conditions previously mentioned, should also be considered. Nevertheless, cardioversion can be accomplished by electrical, chemical, or combined therapies. For a patient with cardiovascular instability, emergency direct current cardioversion (DCCV) is most effective and safe. The patient should be sedated if clinical circumstances allow and treatment begun at 100 J with a biphasic or monophasic pulse. A short-acting benzodiazepine such as midazolam is often the first choice for sedation because it is safe and effective and has amnestic properties as well. The defibrillator should be set to the synchronized mode to synchronize the pulse, if possible, with the QRS deflection, even though the QRS waves occur irregularly. If the initial shock is unsuccessful, the energy of the pulse can be escalated as needed.

Cardioversion can also be accomplished chemically when circumstances allow. Agents that slow conduction or increase the refractory period of atrial tissue are used to break the reentrant microcircuits within the atria. Vaughan-Williams class III and class I medications that can accomplish this goal include ibutilide, amiodarone, procainamide, propafenone, and flecainide. These agents can terminate AF alone and increase the likelihood of cardioversion of AF with subsequent DCCV. However, their use entails some risk. There is an approximately 2% to 5% chance of causing torsades de pointes (TdP) after the infusion of ibutilide, amiodarone, and procainamide because these agents variably increase the duration of the depolarized phase and the associated QT interval in the ventricles, as well as the atria. The newly developed agent vernakalant may be less likely to cause TdP because of its action in blocking the ultrarapid potassium channels located primarily in the atria. Hypokalemia and hypomagnesemia raise the risk for TdP. Pretreatment with magnesium may be protective in some circumstances, even in patients with normal serum electrolyte levels. Propafenone and flecainide can slow conduction, exacerbate heart failure, and cause ventricular dysrhythmias. Cardioversion also carries a risk for embolic stroke.

Fig. 59.3 Electrocardiogram showing atrial fibrillation with no clear P waves and an irregularly irregular ventricular response. Note that the QRS complex is widened in a single beat after a relatively short R-R interval. This is the Ashman phenomenon, which occurs because the His-Purkinje system is still partly refractory to excitation.
AF is associated with unsynchronized, quivering motion of the atrial wall. As a result, there is stasis of blood in the atria and a risk for spontaneous clot formation. AF is an important cause of embolic stroke, with the embolism emanating from the left atrium or its appendage. Long-term anticoagulation with warfarin has been found to reduce the likelihood of embolic stroke, particularly in patients with risk factors, including previous stroke, valvular heart disease, hypertension, diabetes, CHF, and age older than 65 years.

In the acute setting, clot may form within 48 hours after the onset of AF. Cardioversion of AF may cause a new clot to embolize into the systemic circulation. If the patient can clearly discern when he or she is in AF, symptoms have begun within the preceding 1 to 2 days, and the patient is not at high risk for stroke, it is generally safe to perform cardioversion without anticoagulation. However, if there is any uncertainty about the time of onset of the tachydysrhythmia or if it occurred more than 48 hours ago, the patient should not undergo immediate cardioversion. Instead, the cardiology service should be consulted and transesophageal echocardiography performed to search for atrial clot formation, or cardioversion should be deferred until adequate anticoagulation has been established. The only exception would be cardiovascular instability secondary to AF, which requires emergency DCCV. Continuation of anticoagulation should also be considered for 4 weeks after cardioversion because there may be some delay in return of normal atrial contraction.

The disposition of patients with AF depends on a number of factors, including age, comorbid illnesses and social and outpatient medical support, adequacy of control of the ventricular rate, plans for cardioversion, and the state of anticoagulation. If the patient requires ongoing adjustment of medications to control a rapid ventricular response, attempted cardioversion is planned, or new anticoagulation is initiated, hospitalization should be considered. The EP should make this decision in concert with the patient and the consulting cardiologist.

**Multifocal Atrial Tachycardia (MFAT)**

Multifocal AT (MFAT) is a relatively uncommon tachydysrhythmia that primarily affects older patients with chronic lung diseases such as chronic obstructive pulmonary disease, and it appears to be related to the administration of methylxanthine. Its mechanism is uncertain, but MFAT is thought to occur as a result of DADs in atrial tissue triggering ectopic beats. The diagnosis is made on the basis of the following ECG criteria: at least three consecutive P waves with different morphologies, variable P-P and PR intervals, and a heart rate greater than 100 beats/min. Treatment of MFAT is centered on treating the underlying pulmonary disease and possible hypoxia. Antidysrhythmic agents are poorly effective in slowing the atrial rate or the ventricular response or in terminating MFAT. Nevertheless, a carefully administered trial of a calcium channel blocker or amiodarone is reasonable. Generally, beta-blockers should be avoided in patients with any evidence of bronchospasm. Magnesium therapy, particularly in combination with potassium replacement, may slow the rate or terminate the tachydysrhythmia. Patients usually require admission to treat the pulmonary disease.

**Regular Supraventricular Tachycardias**

**Sinus Tachycardia**

Sinus tachycardia may be due to a wide variety of physiologic, pathologic, or pharmacologic causes. If necessary, treatment is usually directed toward the underlying cause. In some settings, such as CHF or acute myocardial infarction (MI), treatment of sinus tachycardia with beta-blockers may improve cardiac hemodynamics and outcome. Sinus tachycardia is often part of the differential diagnosis of other regular tachydysrhythmias. Identifying characteristics of sinus tachycardia are (1) regularly occurring identical P waves with a leftward inferior axis in the frontal plane and (2) gradual onset and offset of the tachycardic rate.

**Atrial Flutter**

Atrial flutter can occur as a result of a variety of cardiopulmonary and metabolic derangements, often in association with atrial dilation. Patients with atrial flutter also tend to experience AF, but atrial flutter is less common overall. The mechanism of atrial flutter is a macroreentrant circuit in the right atrium (see Fig. 59.1, A). The most common variant of atrial flutter is termed typical atrial flutter and involves a counterclockwise wave of roughly circular excitation when viewed from a position facing the front of the patient. The flutter pathway is constrained in the inferior portion of the circular loop by anatomic structures, and it travels between the tricuspid annulus anteriorly and the inferior vena cava and coronary sinus posteriorly. This segment of the pathway, the isthmus, contains the relatively slower-conducting tissue in the reentrant loop. Atypical atrial flutter most commonly travels over the same pathway, but in the opposite direction.

The rate of atrial flutter waves ranges from 250 to 350 beats/min. The diagnosis is made from the ECG tracing, which demonstrates typical sawtooth-shaped flutter waves at the appropriate rate, generally most prominent in the inferior limb leads (II, III, and aVF) and lead V1. The flutter waves tend to be identical and to recur regularly, and there is no isoelectric or flat ECG segment between the waves (Figs. 59.4 and 59.5). As in AF, the refractory period of the AV node usually controls the ventricular response to atrial flutter. The
most common response is 2:1 AV conduction; however, higher, lower, or variable ratios of conduction are also possible. The ratio of conduction depends on the atrial flutter rate, the health of the AV node, and any modifying physiologic, metabolic, or pharmacologic factors. Because atrial flutter is most commonly manifested as flutter waves at 300 beats/min, 2:1 AV conduction, and a ventricular response rate of 150 beats/min, atrial flutter should be the first diagnosis considered in all patients with a regular tachycardia at 150 beats/min. It is important to remember, however, that pharmacologic agents can slow the rate of atrial flutter and decrease or increase AV nodal conduction, thereby altering the usual characteristics.

Management of atrial flutter is similar to that for AF but can be a bit more difficult. Agents that lengthen the refractory period of the AV node tend to gradually decrease the ventricular response rate to AF. In the setting of atrial flutter, the decrease in the ventricular response rate with the same agents may be stepwise and incremental and thus more difficult to control. Furthermore, concomitant slowing of the atrial flutter waves may paradoxically allow greater efficiency of AV nodal conduction. For example, slowing flutter from 280 to 180 beats/min could lead to augmentation of the ventricular response from 2:1 conduction at 140 beats/min to 1:1 conduction at 180 beats/min.

Control of the ventricular rate in patients with atrial flutter can usually be achieved with a calcium channel antagonist such as diltiazem, a beta-blocker, or digoxin. Both electrical cardioversion and chemical cardioversion have a high success rate. Synchronized DCCV should start at 50 J, and the shock should be repeated with higher energy if the first is ineffective. Chemical cardioversion can be achieved with a variety of agents, including class III antidysrhythmics such as ibutilide and amiodarone, class I agents such as procainamide, and the beta-blocker esmolol. Rate control should generally be achieved before attempted chemical cardioversion. These agents can slow the atrial flutter rate with adverse enhancement of the conduction ratio as previously described, or in the case of procainamide or quinidine, the agent’s vagolytic properties may independently enhance AV nodal conduction.

Cardioversion of atrial flutter is associated with thromboembolism, although the association is probably weaker than that with cardioversion of AF. For this reason, cardioversion of atrial flutter should probably not be undertaken in the ED unless the indication is an emergency because of cardiovascular instability, the combined duration of atrial flutter and AF is less than 48 hours, the patient has been adequately anticoagulated before arrival in the ED, or the patient is newly anticoagulated without evidence of atrial thrombi on transesophageal echocardiography. The decision to hospitalize patients with atrial flutter involves weighing issues similar to those described for AF.

**ATRIAL TACHYCARDIA** Regular AT is a relatively uncommon tachydysrhythmia. It may be due to cardiopulmonary disease with dilated atria and a reentrant mechanism; toxicity from digoxin, methylxanthines, or adrenergic agents with increased automaticity; or other causes. AT is distinguished from atrial flutter by separate identifiable P waves with an intervening isoelectric baseline and a rate lower than 200 beats/min (Fig. 59.6). Sometimes the P waves have an abnormal upward or rightward axis, or the onset of tachycardia is abrupt. These characteristics would distinguish the rhythm from sinus tachycardia. Finally, as discussed later, unlike reentrant atrial rhythms that involve the AV node, AT would not be expected to terminate with agents that slow AV nodal conduction. As with atrial flutter, decreasing AV nodal conduction

---

**Fig. 59.5** Electrocardiogram showing atrial flutter at approximately 260 beats/min with regularly irregular 3:2 conduction (3 flutter waves per 2 QRS complexes). Note the variable flutter-to-QRS conduction interval (Wenckebach pattern) and alternating QRS complex morphology. These findings suggest that the heart rate is on the cusp of the refractory period of both the atrioventricular node and the His-Purkinje system.

**Fig. 59.6** Electrocardiogram showing atrial tachycardia at a rate of 163 beats/min with a first-degree heart block and mostly 1:1 atrioventricular (AV) conduction with a single nonconducted beat (see lead V). The abnormal rightward P-wave axis in lead I is not consistent with sinus rhythm. The rhythm is too slow for atrial flutter, and dropped beats would not be expected with a reentrant rhythm involving the AV node and ventricles.
dynamics might slow the ventricular response to the rhythm and facilitate the diagnosis. It would not generally terminate the rhythm because the origin of the tachycardia is contained entirely within the atria.

Treatment of AT begins with assessment of the underlying causes. Digoxin toxicity should be suspected if AT is accompanied by high-grade AV block. Tachycardia in patients with digoxin toxicity results from altered intracellular calcium dynamics and increased excitability, whereas high-grade AV block results from enhanced vagal tone. When there is no evidence of underlying toxicity, ventricular rate control and electrical or chemical cardioversion for AT should be approached as for AF and flutter. If the patient shows evidence of drug toxicity or uncontrolled pulmonary disease or has new tachycardia, admission for further treatment should be considered.

**REENTRANT SUPRAVENTRICULAR TACHYCARDIA**

The nomenclature of reentrant SVTs can be confusing. They are often termed paroxysmal because of their abrupt onset, or they may simply be called SVT. More precisely, they consist of two major subtypes of SVT, AV reentrant tachycardia (AVRT) and AV nodal reentrant tachycardia (AVNRT). Reentrant SVTs are moderately common in both children and adults and most frequently are not associated with other cardiopulmonary disease.

Mechanistically, the two major subtypes of reentrant SVT are distinguished by the route of the reentrant pathway. AVRT uses a macroreentrant circuit with atrial and ventricular segments and connecting segments that involve the AV node and an accessory conducting tract, or rarely, two accessory conducting tracts (see Fig. 59.2, B and C). The AV nodal segment usually serves as the necessary slow-conducting portion of the reentrant circuit.

Many patients have at least two discrete segments that can conduct the input wave of excitability from the right atrium into the AV node. The conducting properties of these inputs may differ, and frequently both a fast-conducting input or pathway and a relatively slow-conducting one are present. Usually, conduction to the AV node is via the fast pathway. AVNRT uses a small macroreentrant circuit consisting of the AV node, right atrial tissue, and connecting fast and slow pathway segments to form a full circle of conduction (see Fig. 59.2, A).

Within each subtype of reentrant SVT, the direction of the wave of excitation can vary. In AVRT, the wave of excitation most commonly proceeds down the AV node and normally through the His-Purkinje system, and it returns in a retrograde direction up the accessory tract to the atria to complete the circuit; this pathway is termed orthodromic conduction (see Fig. 59.2, B). Antidromic conduction occurs when the wave of excitation proceeds in the opposite direction, down the accessory pathway, and returns in retrograde fashion up the AV node (see Fig. 59.2, C). In this case, conduction down the His-Purkinje system and normal, nearly simultaneous excitation of the ventricles do not occur. Rather, the ventricles are activated from the terminus of the accessory tract, and the wave of excitation must propagate across the ventricular myocardium similar to excitation from a premature ventricular contraction (PVC). Consequently, it takes longer to excite the entire ventricular muscle mass, and the corresponding QRS wave is widened with antidromic conduction.

Reentrant SVTs are usually easily diagnosed from the ECG. The most common finding is a narrow QRS complex tachycardia at rate of 120 to 250 beats/min. The atria are activated in a retrograde direction from the AV node or an accessory tract. In AVRT, retrograde P waves that are inverted in V1 and the inferior leads may be observed just after the QRS complex (Fig. 59.7). In AVNRT, retrograde excitation of the atria is often simultaneous with ventricular excitation, and retrograde P waves are not observed because they are hidden or buried within the QRS complex (Fig. 59.8). In this case, P waves appear to be absent.
Reentrant SVT may be manifested as a wide QRS complex primarily for two reasons. Normal rapid conduction down the His-Purkinje system leads to nearly simultaneous excitation and depolarization of the ventricular myocardium and a narrow QRS complex on the ECG. If the left or right bundle of the Purkinje system fails to conduct, the QRS complex is widened and displays bundle branch block (BBB) morphology (see Fig. 59.2, F). This can occur as a result of intrinsic conduction system disease and chronic BBB, or the failure may be rate dependent and occur only during tachycardia. The other reason for a widened QRS complex is AVRT with antidromic conduction antegrade down the accessory pathway (see Fig. 59.2, C). This path does not use the His-Purkinje system, and a widened QRS complex without typical BBB morphology would be expected.

Particularly in children, reentrant SVTs are usually well tolerated. Patients with more rapid heart rates are more prone to cardiovascular instability, including hypotension and presyncope. Patients may also feel palpitations, dyspnea, and chest pain, which can be due to myocardial ischemia.

From an ED perspective, it is not usually important to distinguish AVRT from AVNRT. The acute treatment and prognosis for the two conditions are the same. Vagal maneuvers should be attempted or drugs administered to slow conduction and increase the refractory period through the AV nodal tissue so that the node is refractory to excitation and conduction when the reentrant wave approaches it. Agents such as adenosine and calcium channel blockers act directly on the nodal tissue, whereas other interventions, such as vagal maneuvers, digoxin, and beta-blockers, may alter vagal or adrenergic tone (Box 59.2). Adenosine may be the optimal agent because it is highly effective and safe with an ultrashort (9-second) half-life in serum. Rapid clearing, however, can be a disadvantage if the tachydysrhythmia is recurrent. In this case, the calcium channel blocker verapamil may be useful because it is equally effective for termination and may prevent recurrent episodes. Verapamil should not be used in infants, however, because of the risk for cardiovascular collapse.

Physiologic maneuvers that increase vagal tone, such as immersion of the face in iced water, massage of the carotid bulb, and the Valsalva maneuver, may also be effective but have the same potential disadvantage of recurrence of the tachycardia. Iced water immersion may be more effective and better tolerated in children. Carotid massage should not be attempted in adults until a carotid bruit has been ruled out by auscultation. As for other supraventricular tachydysrhythmias, synchronized DCCV should be reserved for patients who demonstrate cardiovascular instability. Most patients can be discharged home after termination of reentrant SVT. Hospitalization should be considered for those whose tachydysrhythmia is recurrent or associated with cardiovascular instability.

**PREEXCITATION (WOLFF-PARKINSON-WHITE) SYNDROME** When a patient has an accessory pathway myocardial fiber connecting the atria and ventricles with evidence of antegrade conduction down this pathway, the patient has preexcitation, or WPW, syndrome. The syndrome is uncommon, is usually diagnosed in children or young adults, and is most commonly not associated with other cardiopulmonary disease. Patients may be in normal sinus rhythm or have a variety of supraventricular tachydysrhythmias, including AVRT in 80% of cases, AF in 15% to 30%, and atrial flutter in 5%. Approximately 85% of AVRT episodes have an orthodromic direction of activation, and 15% are antidromic.

The diagnosis can be made while the patient is in normal sinus rhythm if the following characteristics are observed on the ECG: (1) shortened PR interval (<120 msec), (2) widened QRS complex beyond 120 msec, and (3) atypical initiation of the QRS complex with a delta-wave morphology (Fig. 59.9). Associated ST-T wave abnormalities are often present, with the T wave inverted with respect to the delta wave and QRS complex. These three diagnostic abnormalities are easily understood from an electrophysiologic perspective (see Fig. 59.2, D).

In normal sinus rhythm, the wave of excitation can propagate down both the AV node and the accessory pathway. Because the accessory pathway does not contain slow-conducting tissue, the wave traverses the accessory pathway and reaches the ventricular myocardium before traversing the AV node. The shortened PR interval and early delta wave upstroke of the QRS wave are due to preexcitation of the
ventricle via the accessory pathway. Eventually, the atrial excitation wave also traverses the AV node, and once this occurs, it will move rapidly through the specialized rapid-conducting His-Purkinje system. In the meantime, the wave that has traversed the accessory pathway propagates slowly through the ventricular myocardium because it does not use the Purkinje fibers for rapid transmission. Consequently, the QRS deflection arrives early with a delta wave, but the latter portion normalizes as a result of the influence of normal AV nodal conduction. Because of the atypical pattern of ventricular depolarization, repolarization changes in the form of ST-T abnormalities are expected.

Patients with WPW syndrome are predisposed to AVRT, as well as to AF and atrial flutter, which often demonstrates a rapid ventricular response. The pathway of conduction of the AF wavelets from the atria to the ventricles depends on the relative refractory period of the accessory pathway with respect to the AV node. The slow-conducting cells of the AV node have a long refractory period, and the refractory period of the accessory conducting tissue is usually shorter. Consequently, the AV node remains refractory when the accessory pathway tissue is repolarized and ready for conduction. In WPW syndrome, AF usually conducts down the accessory pathway with a rapid ventricular response rate that is determined by the refractory period of the accessory conducting tissue (Fig. 59.10; also see Fig. 59.2, E). Similar to the situation with normal sinus rhythm, the ventricles are activated from the ectopic accessory pathway terminus, and an irregularly irregular tachycardia with a wide QRS complex results.

Perhaps the greatest concern regarding patients with WPW syndrome is their higher risk for sudden cardiac death. This risk is inversely associated with the minimum refractory period of the accessory conducting tissue. The mechanism of sudden cardiac death is thought to most commonly be AF with accessory tract conduction and a dangerously high ventricular response rate that causes ischemia and electrical instability and degenerates to VF.

It is important to remember that like the AV node and other cardiac tissue, accessory pathways have dynamic electrophysiologic properties that may vary with the hormonal, physiologic, or pharmacologic milieu. However, in this respect, accessory pathway tissue behaves more like myocardium and less like AV nodal tissue, which is highly sensitive to vagal stimulation. Depending on the current milieu, conduction in many patients with WPW syndrome may variably occur primarily down the accessory pathway or the AV node in normal sinus rhythm, and this variation even occasionally occurs in AF (Fig. 59.11).

Treatment of AF with rapid ventricular response in patients with WPW syndrome must be approached differently. The usual treatment of AF is to administer agents that increase the refractory period of the AV node and slow AV nodal conduction. Because conduction is primarily down the accessory pathway in WPW syndrome, treatment must be directed toward lengthening the refractory period of the accessory pathway tissue, not the AV node. Paradoxically, agents that block AV nodal conduction, such as beta-blockers, calcium channel blockers, adenosine, and digoxin, may also cause vasodilation, decrease contractility, or have other effects that reflexively increase adrenergic tone or stimulate and enhance accessory pathway conduction. For this reason, these agents should not be used.

The preferred pharmacologic agents for patients with WPW syndrome and AF with a rapid ventricular response are the class IA antidysrhythmic agent procainamide and, possibly, class III medications such as amiodarone and sotalol. These antidysrhythmics are used to decrease the ventricular response rate, and they may also terminate AF. Nevertheless, they have multiple potential dangers and must be used with caution. All these antidysrhythmics can decrease blood pressure. When administered intravenously, amiodarone blocks AV nodal conduction, so the concerns already described with other AV nodal blocking agents may be applicable. The safest and most effective treatment for patients with WPW syndrome is their higher risk for sudden cardiac death. This risk is inversely associated with the minimum refractory period of the accessory conducting tissue.
waves may be present with evidence of AV dissociation. Alternatively, retrograde nodal-to-atrial conduction with abnormal P waves and a superior axis occurring after the QRS deflection may be seen. P waves may be absent if atrial depolarization occurs simultaneously with ventricular depolarization.

Digoxin toxicity is an important cause of junctional tachycardia. In particular, digoxin toxicity should be suspected when the rapid ventricular response to AF becomes regular during digoxin treatment. Diagnosis and treatment should focus on identifying and addressing the underlying cause, including reversal of toxicity, if any. Digoxin immune Fab fragments (Digibind) may be necessary for the cardiovascular instability associated with digoxin toxicity, and DCCV should be avoided if possible. Most patients require admission until the underlying disease or toxicity is resolved.

VENTRICULAR TACHYCARDIAS

Premature Ventricular Contractions and Nonsustained Ventricular Tachycardia

PVCs are common. They can occur chronically with no associated cardiac disease or can develop in association with acute cardiopulmonary or metabolic derangements. Some specific causes include:

• Cardiac ischemia, which may be due to local coronary artery disease or systemic hypoxia
• Heart failure with increased myocardial stretching
• Inflamed myocardium
• Electrolyte imbalance
• A vast array of medications and toxins

There is a spectrum of frequency of ventricular ectopy. PVCs may occur singly in isolation, or a PVC may occur every second or third beat, an arrhythmia termed bigeminy or trigeminy, respectively. Three or more ventricular beats in a row at a rate greater than 100 beats/min is defined as VT. If the
consecutive ventricular beats resolve spontaneously or terminate within 30 seconds, the VT is nonsustained (NSVT).

All the major dysrhythmic mechanisms described, including enhanced automaticity, triggered beats, and reentry, may be involved in the development of PVCs and NSVT. Irregular cardiac contractions interspersed with a regular rhythm can be heard on cardiac auscultation or felt on examination of the pulse. However, the diagnosis is usually made by examining the ECG tracing. The QRS deflections are wide because the ectopic ventricular beats generally do not use the specialized Purkinje conduction system, and the T wave is usually large and inverted with respect to the QRS complex. No premature P wave precedes the ventricular beat, but there may be a visible or hidden inverted retrograde P wave following it. Patients may be asymptomatic, or they may feel palpitations and discomfort from the ectopic beats. If the frequency of ectopic ventricular beats or the rate of NSVT is sufficiently high, hemodynamic compromise with hypotension, presyncope, or CHF may be present.

Chronic ventricular ectopy does not generally require emergency treatment, and suppression of chronic ventricular ectopy after MI does not lower the mortality. Patients with chronic PVCs may be at variably higher risk for sudden death, depending on other clinical factors, but even so, it is often unclear whether the increased risk is directly attributable to the ectopy or to the underlying cardiac disease. EPs must commonly manage new ventricular ectopy in association with acute MI or other severe systemic disease. The greatest concern is that PVCs may induce sustained VT or VF. Theoretically, this could occur if the ectopic ventricular depolarization occurs during the vulnerable period or upstroke of the T wave of the preceding beat (R-on-T phenomenon).

The risk for VF and sudden death is elevated during acute MI, but this risk is not decreased with routine suppressive class I antidysrhythmic therapy. Conversely, beta-blockade with metoprolol may not affect the occurrence of PVCs or NSVT but does lower the rate of VF and death. Suppression of new ventricular ectopy should be considered if the PVCs or tachydysrhythmias are symptomatic and contributing to hemodynamic instability or the patient has already experienced sustained VT or VF. The first priority is to search for reversible causes of ventricular ectopy, such as hypoxia; potassium, magnesium, or other electrolyte imbalance; or drug toxicity. After reversible causes are addressed, the most commonly used agents include beta-blockers, amiodarone, lidocaine, and procainamide. The class I effect of myocardial sodium channel blockade may be particularly prominent for lidocaine in an ischemic and acidic local cellular environment. Evidence suggests that amiodarone may be effective when lidocaine fails. The antidysrhythmics should be given as a loading dose followed by a maintained infusion, and the patient should be monitored closely for adverse effects and admitted to a cardiac care unit.

**Monomorphic Ventricular Tachycardia**

VT is considered sustained if it is continuous for at least 30 seconds. If the QRS complex has primarily a single morphology, the VT is monomorphic, whereas if the QRS complex varies, the VT is polymorphic. Monomorphic VT is an uncommon condition that underlies the chief complaint in approximately 1 in every 10,000 ED visits. The mechanism in the majority of cases is reentry within the ventricular myocardium, where the slow-conducting segment of the reentrant loop is associated with a scar from a previous MI (see Fig. 59.1, B). The scar tissue serves to enable and fix the location of the VT circuit within the myocardium. Other causes of monomorphic VT that are less commonly encountered in the ED are dilated cardiomyopathy, hypertrophic cardiomyopathy, previous surgical repair of congenital heart disease with a myocardial scar, arrhythmogenic right ventricular dysplasia, right ventricular outflow tract VT, and fascicular tachycardia.

Patients with VT may experience palpitations, lightheadedness, chest discomfort, dyspnea, or more progressive cardiovascular compromise. The heart sounds and pulse are regular and rapid. Approximately half the patients have separate atrial activity with AV dissociation, evidence of which can occasionally be detected on physical examination as variable intensity of the first heart sound or arterial or jugular venous pulsations. The ECG tracing demonstrates a regular wide QRS complex tachycardia without preceding P waves. Nonetheless, it can be difficult to differentiate VT from SVT with a wide QRS complex because of aberrant or antegrade accessory pathway conduction. The next section addresses this issue specifically. Ultimately, the diagnosis can be most accurately determined when synthesizing combined information from the medical history, physical examination, and ECG.

Treatment of monomorphic VT depends on the patient’s cardiovascular status. The patient's condition can be categorized as pulseless, unstable, or stable. Pulseless VT should receive the same treatment as VF: immediate chest compressions and initial shock using unsynchronized 200 J with a biphasic or monophasic waveform as soon as defibrillation is available.

Patients are unstable if they have a pulse but also symptoms of lightheadedness, chest pain, dyspnea, other signs of inadequate perfusion of vital organs, or frank hypotension. Patients with unstable VT should undergo cardioversion using synchronized 100 J with a biphasic or monophasic waveform. An awake patient should receive prehydration as long as it would not significantly delay DCCV.

Patients with stable VT may initially be treated with medical or electrical therapy. The primary principle of treatment with class I or III antidysrhythmic agents is to prolong the refractory period of the ventricular myocardium so that the cells remain refractory when the reentrant wave of excitation returns. Amiodarone is recommended by the American Heart Association, and procainamide and sotalol can be used as alternatives when cardiac output seems to be clinically preserved. Lidocaine is no longer recommended for this purpose. Unfortunately, neither amiodarone nor lidocaine immediately increases the refractory period of normal myocardium after intravenous administration. Both are unlikely to terminate VT within 20 minutes of treatment. However, amiodarone may become more effective in both terminating and preventing VT over the ensuing hours after administration. Procainamide and racemic sotalol do prolong the refractory period soon after administration and are more likely to terminate VT. However, procainamide blocks cardiac sodium channels, and the l isomer of sotalol is a beta-blocker; thus, both agents can cause a decrease in cardiac contractility and subsequent hemodynamic instability. Intravenous sotalol is not currently available in the United States. Other agents that have been
used in this situation are pure beta-blockers and magnesium. Neither has been proved to be effective, however, and pure beta-blockers may cause hypotension.

The safest and most effective treatment of stable monomorphic VT remains DCCV. Initial DCCV should be particularly considered in patients with ventricular rates greater than 150 beats/min because they are at higher risk for compromised cardiac output and hemodynamic collapse. Cardioversion using synchronized 100 J with a biphasic or monophasic waveform should be performed after appropriate sedation. If the patient already has an internal implantable cardioverter-defibrillator (ICD), overdrive pacing or synchronized cardioversion may be performed by the device automatically or manually at the bedside by the electrophysiologist. Suppressive treatment with antidysrhythmic agents should be considered if the VT is recurrent. Over a period of hours, intravenous amiodarone or procainamide is likely to be the most effective of the agents currently available in the United States. If procainamide is used, it should be loaded slowly over a period of approximately 1 hour and the patient monitored closely for hypotension. Generally, infusion of multiple antidysrhythmics should be avoided because it might increase the likelihood of adverse effects. Most patients with monomorphic VT should be admitted for observation and further treatment.

**WIDE QRS COMPLEX TACHYCARDIA: DIFFERENTIATING SUPRAVENTRICAL FROM VENTRICULAR TACHYCARDIA**  Wide QRS complex tachycardia may be due to an SVT with aberrant His-Purkinje conduction or antegrade conduction down an accessory pathway or be due to VT. Diagnosis of the underlying mechanism is important for a number of reasons. The optimal short- and long-term treatment and prognosis may vary considerably, depending on the mechanism involved. The history, physical examination, and ECG findings can be used to make the diagnosis (Box 59.3). In the ED, the pretest probability favors VT by a ratio of 2:1 to 3:1.

No single historical factor has been found to be both sensitive and specific for diagnosing VT. Nevertheless, age older than 35 years and male sex are sensitive for VT, and a previous history of MI or coronary artery bypass graft surgery, recent angina, or CHF is a specific predictor of VT. The primary underlying theme for all these predictors is a greater likelihood of coronary artery disease and previous infarction with scar formation. In fact, the strongest single historical predictor of VT is a history of MI, which has a positive likelihood ratio of 13:1 to 20:1 and a negative likelihood ratio of 0.36.

A number of approaches may be used to diagnose wide QRS complex tachycardia from the physical examination. Perhaps the first and most important principle to remember is that apparent hemodynamic stability does not rule out VT. AV dissociation is present about half the time in patients with VT. When it is present, the atria are contracting independently of the ventricles, so the atria may either contract during ventricular diastole and assist cardiac output or contract against closed valves during ventricular systole with a large retrograde venous pulsation. The EP can assess for beat-to-beat variation of the first heart sound or systolic blood pressure or for large cannon jugular venous waves. Unfortunately, even under controlled experimental conditions, none of these findings are both sensitive and specific. In clinical conditions in which about half the patients have some form of retrograde ventricular-atrial conduction, these tests for physical evidence of AV dissociation can approach a sensitivity for VT of only approximately 50% at best.

Vagal maneuvers, such as carotid sinus massage or the Valsalva maneuver, can be performed to increase vagal tone and alter AV nodal conduction. Depending on the type of SVT, vagal maneuvers could terminate a reentrant rhythm involving the AV node or temporarily decrease the ventricular response to a purely atrial rhythm such as atrial flutter. Termination of wide QRS complex tachycardia with vagal maneuvers would suggest a supraventricular rhythm because most forms of VT are not responsive. Temporary slowing of the ventricular response to an atrial tachydysrhythmia could be diagnostic.

A similar principle of brief increased refractoriness of the AV node underlies the use of adenosine to diagnose and treat wide QRS complex tachycardia. The combined response to a 12-mg bolus of adenosine—either termination of the tachycardia or transient ventricular slowing—has a sensitivity of 90% and a specificity of 98% for an underlying SVT. Considered in reverse fashion, “nonresponse” to a 12-mg bolus of adenosine would have a positive likelihood ratio of about 9 and a negative likelihood ratio of 0.03 for VT. This test is useful for diagnosis, but is it safe?

The primary safety concern is the administration of adenosine to patients with atrial flutter and antegrade accessory pathway conduction, which might cause subsequent transient acceleration of this conduction and the ventricular response. This and other destabilizing scenarios have been reported after the administration of adenosine to patients with wide QRS complex tachycardia secondary to VT and SVT. Adenosine should never be given to patients with a rapid, irregularly irregular wide QRS complex tachycardia because it may actually be AF with accessory pathway conduction, and acceleration of the ventricular response has been reported in this situation as well. Nonetheless, the adverse affects previously
described after adenosine administration to patients with regular wide QRS complex tachycardia are rare. Multiple consecutive case series have found no greater rate of adverse effects with adenosine than with other antidysrhythmic medications.27,28 Adenosine should be used as a diagnostic and therapeutic agent for regular wide QRS complex tachycardia when the history, physical examination, and ECG findings suggest a supraventricular origin. The EP should ensure that the adenosine is used properly—administered as a 12-mg rapid bolus dose followed immediately by a normal saline bolus flush, with a cardioverter-defibrillator immediately available in the event of destabilization.

A number of ECG findings can be used to diagnose wide QRS complex tachycardia. Possible differentiating characteristics include the heart rate, frontal axis of the QRS deflection, concordance across the precordial leads, QRS duration, morphology of the QRS complex, AV dissociation, and capture or fusion beats. On average, wide QRS complex tachycardia secondary to VT has a faster heart rate than that secondary to VT.25 This difference has been slightly augmented in the recent past with the use of ICDs. A patient with VT may have already received an ICD, which is preferentially programmed to treat rapid VT, usually greater than 160 to 180 beats/min. It cannot be programmed to treat slower VT because of the risk for inappropriate pacing or shocks for sinus tachycardia. Nevertheless, there is still too much overlap in the heart rate of patients with SVT and VT to use it as a firm differentiating factor. Regardless of the underlying rhythm, higher heart rates are associated with compromised cardiac output because of inadequate diastolic filling and greater electrical instability. Immediate DCCV should be considered for patients with rapid wide QRS tachycardia, regardless of the presumed etiology.

Because of the common ectopic left ventricular origin of the rhythm in VT, abnormal upward and rightward propagation of the excitation wave may be seen. In fact, the QRS axis may point to any of the four quadrants in VT, but an upward and rightward QRS axis is highly unusual for SVT. This finding, defined by a negative QRS deflection in leads I and aVF, is insensitive (24%) but highly specific (100%) for VT (Fig. 59.12).29 An abnormal QRS vector that points toward or away from all of the precordial leads simultaneously is also indicative of VT. A QRS deflection that is primarily positive in all of the precordial leads is defined as positive concordance. The finding of primarily negative QRS deflections in all precordial leads is defined as negative concordance. Each of these findings is also insensitive (10%) but specific (85%) for VT.29

On average, the duration of initial depolarization as recorded by the QRS wave is longer with VT than with wide QRS complex SVT. A QRS duration greater than 140 msec with a right BBB (RBBB) pattern or a QRS duration greater than 160 msec with a left BBB (LBBB) pattern is insensitive but more than 90% specific for VT.29 Brugada et al.30 modified this concept and found that an RS interval greater than 100 msec in the precordial leads has a sensitivity of 66% and a specificity of 98% for VT (Fig. 59.13). Unfortunately, the high specificity of these findings is not applicable if the patient has received a medication that widens the QRS complex, such as a class I antidysrhythmic.

QRS morphology may be helpful, particularly if an old ECG is available. QRS morphology with tachycardia similar to a previous BBB morphology noted in sinus rhythm may suggest, but does not prove VT.11 The distinction of RBBB versus LBBB is itself not helpful, but various morphologic variants within these two categories can at least be theoretically helpful.24,25,30

When present, the most definitive evidence of VT is AV dissociation. In SVT an atrial contraction is associated with each ventricular beat. AV dissociation is defined by atrial activity that is separate and independent of ventricular contractions (Fig. 59.14). AV dissociation is present in about half of VT episodes, and it can be seen on the ECG in half of these cases, or about one quarter of all VT episodes. Thus, AV dissociation has a sensitivity of about 25% and specificity approaching 100% for VT. Dissociated P waves should be sought in the V₁ rhythm strip, where they are usually most
Visceral Disorders

Cardiac Disorders

Fig. 59.14  Electrocardiogram showing ventricular tachycardia with atrioventricular dissociation. Although the QRS complexes are relatively narrow, there is clear evidence of atrioventricular dissociation in the V1 rhythm strip.

Fig. 59.15  Electrocardiogram showing ventricular tachycardia with a single capture beat.

easily seen. The key is to find two candidate P waves. One can then look an equal distance on each side of these two waves for a third deflection. If three consecutive deflections are found that “march out,” they are probably P waves; such identification can be confirmed by marching out more on the ECG. Fusion beats represent fusion of supraventricular excitation mediated by the His-Purkinje system and local ventricular excitation. Capture beats signify complete ventricular depolarization by a supraventricular signal and usually have a narrow QRS complex. Both these phenomena also suggest AV dissociation and VT (Figs. 59.15 and 59.16).

Severe hyperkalemia can also cause wide QRS complex tachycardia. Clues to this diagnosis include a history of renal failure or other medical causes of hyperkalemia and an ECG with very wide and bizarre QRS complexes (Fig. 59.17). Once the condition is diagnosed, it should be confirmed with a serum potassium measurement and treated with intravenous calcium, insulin, glucose, and bicarbonate. Patients who overdose with cyclic antidepressants or other sodium channel blocking agents may have a wide QRS complex tachycardia. An important clue to this diagnosis on the ECG is right axis deviation of the terminal 30 msec of the QRS complex. Patients with suspected overdose should be treated with a continuous intravenous sodium bicarbonate infusion. Patients with acute respiratory distress secondary to pulmonary disease and with an underlying BBB may appear to have a primary tachydysrhythmic condition. Addressing the airway, with intubation if necessary, may slow the heart rate, expose the P waves, and clarify the rhythm.

Finally, in a significant proportion of cases it may not be possible to make a definitive ED diagnosis. In some cases of VT the bundle branches may be used as part of the reentrant limb, thereby mimicking aberrant conduction, and excitation of the ventricles via an accessory pathway may give an ECG appearance of VT. When the diagnosis is in doubt, the safest approach is to sedate the patient, perform DCCV, and leave the definitive diagnosis for the electrophysiologist.

Polymorphic Ventricular Tachycardia

Polymorphic VT is defined as VT with varying QRS wave morphology (Fig. 59.18). A specific type of polymorphic VT characterized by sinusoidal variation of the QRS deflection occurs in patients with a long QT interval during sinus rhythm (Fig. 59.19). This tachydysrhythmia is termed torsades de pointes (TdP), or “twisting of the points” (Fig. 59.20). There are a number of causes of polymorphic VT and TdP, which itself is an important cause of sudden cardiac death. Fortunately, this tachydysrhythmia is rare.

Polymorphic VT in the setting of a normal QT interval is most often associated with acute cardiac ischemia. It is a rare but important indicator of ongoing ischemia. The most important treatment is revascularization therapy. Pending revascularization, suppression of the dysrhythmia can be attempted with lidocaine or amiodarone.

Polymorphic VT in association with a long QT interval can be due to a congenital or acquired cause. The mechanisms involved in initiation and propagation of this form of polymorphic VT termed TdP are not entirely understood. Prolongation of the QT interval itself may not cause TdP but may lead to secondary phenomena that initiate TdP. Such phenomena are increased QT dispersion and EADs. QT dispersion refers to the maximum variation in the QT interval observed in the 12 leads on the ECG tracing. If the QT interval and corresponding refractory period of the myocardium have increased heterogeneity, partial and abnormal depolarization of cells may occur, particularly after an EAD with subsequent loss of synchrony. Spiral reentrant waves can result, but the prolonged QT interval may determine the geometry and appearance of polymorphic VT as opposed to frank VF.
Cellular repolarization and the QT interval vary as a function of the preceding heart rate. Thus, the measured QT interval is corrected for the heart rate, most commonly with the Bazett formula. After puberty, on average, women have a slightly longer QT interval than men do (Table 59.2), and a variety of medications can prolong the QT interval. Patients with a prolonged QT interval are asymptomatic unless TdP or another tachydysrhythmia develops, which may be manifested as syncope or sudden cardiac death.

Congenital long QT syndrome with TdP is due to a growing number of known ion channelopathies (Table 59.3). The most common defects lead to deficient potassium channel conduction and augmentation of sodium channel conduction, which cause a prolonged QT interval. Other genetic abnormalities associated with polymorphic VT and sudden cardiac death are rare calcium channel defects, ion channel defects leading to a shortened QT interval, and Brugada syndrome, which is attributed primarily to premature inactivation of

*A single mutation (heterozygous state) in any of the genes responsible for LQTS1 through LQTS7 results in an autosomal dominant form of illness (Romano-Ward syndrome). Two mutations (homozygous state) in LQTS1 or LQTS5 result in a more severe autosomal recessive illness with associated deafness (Jervell and Lange-Nielsen syndrome).
†Defects in SCN5A have been identified in only 20% to 30% of cases.
sodium channel conduction. As with hemoglobinopathies, there appear to be a wide variety of defects associated with myocardial conducting channels and their supporting proteins, and they are associated with varying risk for tachydysrhythmias and mortality.

The possibility of congenital long QT interval should be considered in all patients with palpitations, presyncope, syncope, or seizures. What were the circumstances of the event, and has the patient previously had similar events? Did the onset of symptoms occur during rest, sleep, or activity or after the patient was startled (see Table 59.3)? How long did the symptoms last, and were there any associated symptoms of chest pain or shortness of breath? Many of these conditions exhibit autosomal inheritance, although new mutations are common. The family history should be assessed for recurrent syncope and sudden death.

In a patient with sinus rhythm, the physical findings are usually normal. However, analysis of the QT interval and T-wave morphology on the ECG is critical. Different channelopathies tend to be associated with specific T-wave abnormalities. Assess for the morphology of Brugada syndrome, an RBBB pattern in the precordial chest leads with associated downsloping ST-segment elevation (Fig. 59.21). Search for evidence of other cardiologic causes of syncope, including

*The QTc values (sec) are derived from the measured QT interval in seconds divided by the square root of the R-R interval in seconds. From Moss AJ. Measurement of the QT interval and the risk associated with QTc interval prolongation: a review. Am J Cardiol 1993;72:23B-25B.

---

**Fig. 59.19** Defining the QT interval. The QT interval starts at the beginning of the Q wave—or the R wave if no Q wave is present—and ends when the T wave returns to the baseline.

**Fig. 59.20** Three-lead electrocardiogram tracing demonstrating normal sinus rhythm with a prolonged QT interval and torsades de pointes. Note the classic long-short pattern of initiation. A premature ventricular contraction (left arrowhead of the red arrow) causes a subsequent long R-R interval (red arrow). The long R-R interval causes a particularly long QT interval in the next beat (green arrow). This beat with a long QT interval is particularly susceptible to depolarization during the vulnerable relative refractory period of the T wave and initiation of torsades de pointes as shown.

**Fig. 59.21** Electrocardiographic tracings from septal precordial leads with an incomplete right bundle branch block and downsloping ST-segment elevation consistent with Brugada syndrome.
preexcitation and WPW syndrome, ventricular hypertrophy, aortic valvular disease, and other tachydysrhythmias or bradydysrhythmias. Serum electrolytes, including potassium, calcium, and magnesium, should be measured, and treatment should be administered as needed.

Acquired long QT syndrome is due to toxicity from medications that either prolong the QT interval or block the metabolism of QT-prolonging agents (Box 59.4). Medications that prolong the QT interval act by altering ion channel flow, such as by disrupting the outward potassium repolarizing current. Women are more prone to acquired long QT syndrome, perhaps in part because of their longer baseline QT interval. Acute symptoms are similar to those in the congenital form of disease.

Treatment of TdP involves immediate unsynchronized defibrillation if the patient is unstable or pulseless. An initial energy of 200 J should be used for biphasic defibrillation or 360 J for a monophasic waveform. Synchronized DCCV is not usually recommended because of the variability of the QRS waveform and potential failure to synchronize. Magnesium should be administered to terminate TdP and possibly to prevent recurrences. Increasing the heart rate reduces the QT interval. The heart rate can be increased by external or internal pacing or with the administration of isoproterenol. Class I and III antidysrhythmic agents are generally contraindicated because they may further prolong the QT interval and increase QT dispersion. Removal of the offending agent should be considered in patients with acquired QT prolongation, although this step is not usually feasible. Patients with polymorphic VT and TdP require admission to a monitored unit for further evaluation and treatment.

**SUMMARY**

ED disposition of a patient with a tachydysrhythmia depends on the diagnosis, if known; symptoms of cardiovascular instability, including presyncope, chest pain, or shortness of breath during tachycardia; the patient’s underlying cardiovascular health; and the patient’s social support and medical follow-up. Patients with known recurrent supraventricular tachydysrhythmias that are well tolerated hemodynamically can usually be discharged with close follow-up. Generally, patients with a new-onset, undiagnosed, or ventricular tachydysrhythmia should be admitted.

The long-term and definitive care of patients with dysrhythmias has advanced remarkably. Definitive catheter ablation can be performed on selected patients with AF, atrial flutter, AVT, AVNRT, and VT. ICDs are commonly implanted in patients with ventricular tachydysrhythmias or a low ejection fraction after MI. Patients may also require adjunctive oral antidysrhythmic therapy to minimize ICD shocks. The EP should expect to see more patients with intracardiac devices and advanced treatments in the future. Optimal ED care of these patients will require sound understanding of the clinical issues, familiarity with new technologies, and close collaboration with cardiology colleagues.

60 Pericarditis, Pericardial Tamponade, and Myocarditis

Amal Mattu and Joseph P. Martinez

KEY POINTS

- The classic symptom of acute pericarditis is sharp, pleuritic retrosternal chest pain that radiates to one or both trapezius ridges and changes with body position.
- The hallmark electrocardiographic findings in patients with pericarditis include diffuse ST-segment elevation with PR-segment depression in the same leads.
- High-dose aspirin or a nonsteroidal antiinflammatory drug with the addition of colchicine is effective treatment of most cases of acute pericarditis.
- Steroids should be avoided in the early treatment of first-time pericarditis because their use may actually increase the chance of recurrence.
- Large pericardial effusions often cause severe tachypnea and dyspnea; however, oxygen saturation levels are usually normal.
- Jugular venous distention is typical in patients with pericardial tamponade, but it may be absent in those with hypovolemia or if the tamponade developed rapidly.
- The hallmark echocardiographic finding in patients with pericardial tamponade is the presence of a large effusion with diastolic collapse of the right heart chambers.
- The classic manifestation of acute myocarditis includes low-grade fever, tachypnea, and tachycardia out of proportion to the fever.

EPIDEMIOLOGY

Although the greatest concern in patients with chest pain is usually vascular causes of chest pain—acute coronary syndrome, pulmonary embolism, and aortic dissection—other less common, but potentially deadly illnesses must be considered, including pericarditis, pericardial tamponade, and myocarditis.

Acute pericarditis is often subclinical, so its incidence is uncertain. However, rough estimates range from 2% to 6%, and this disorder may be responsible for as many as 1 in every 1000 hospital admissions. Although acute pericarditis is not usually deadly, it can be painfully disabling if not treated appropriately.

Pericardial tamponade is a potentially deadly result of pericardial effusion. Such an effusion can develop from pericardial inflammation or cardiac trauma. Unfortunately, the early features of tamponade can mimic those of other diseases and lead to initial misdiagnosis.

Acute myocarditis is relatively uncommon, but it is a devastating condition that can occur and progress quickly, with little warning. The initial findings can vary from mild, viral-type symptoms to fulminant cardiogenic shock.

PERICARDITIS

PATHOPHYSIOLOGY

The pericardium is the layer of tissue surrounding the heart. It consists of two layers, a serous inner layer (visceral pericardium) and a fibrocollagenous outer layer (parietal pericardium). The pericardium completely encloses the ventricles and the right atrium; a portion of the left atrium remains outside the sac. A thin layer of plasma fluid (usually 15 to 30 mL) separates the visceral and parietal pericardial layers and acts as a lubricant. The main function of the pericardium appears to be provision of ligamentous stability to withstand forces against the heart. It also provides some shielding for the heart. Despite these apparent functions, however, the majority of patients who undergo pericardectomy do not appear to suffer any decrease in cardiac performance or other ill effects.

Pericarditis refers to inflammation of the layers of the pericardium. It has many possible causes (Box 60.1), but in most cases the cause is unknown. In the majority of these idiopathic cases the presumed cause is viral, although most attempts to prove a viral cause have low yield. The most common viral cause is coxsackievirus B. The most common cause of pericarditis worldwide is tuberculosis.

PRESENTING SIGNS AND SYMPTOMS

CLASSIC

Chest pain is the typical complaint of patients with acute pericarditis. Classically, the chest pain is sharp, retrosternal, and pleuritic, and it radiates to one or both trapezius ridges...
because the phrenic nerve, which traverses the pericardium, innervates these muscles. Typically, the pain also changes with body position: it improves when the patient sits up and leans forward and worsens when the patient lies supine.

The physical examination of patients with acute pericarditis is usually nondiagnostic. Although some researchers report the presence of a friction rub in up to 85% of patients at some point in the course of the disease, the presence of a friction rub at the time of initial evaluation is unreliable. When a friction rub is present, it is best heard at the left sternal border at end-expiration with the patient leaning forward. The rub is usually described as consisting of three components that correspond to atrial systole, ventricular systole, and rapid diastolic filling. A friction rub is thought to be caused by rubbing of the inflamed layers of the pericardium against each other.

**TYPICAL VARIATIONS**

The typical findings in patients with acute pericarditis may not always be present. Although chest pain is the most common symptom, patients sometimes have dyspnea as the primary complaint. When chest pain is present, it is not always positional or pleuritic, and it may not always radiate to the trapezius ridge. Patients may also complain of cough, upper respiratory symptoms, nausea, or vomiting, which may mislead the physician to an alternative diagnosis. Patients with bacterial infections are likely to have complaints of fever, and patients with tuberculous pericarditis are likely to report a chronic cough, weight loss, and night sweats.

Although the presence of a triphasic friction rub is classic, it actually occurs in only half of patients with pericarditis. The physical findings may also be notable for hypotension and jugular venous distention in the presence of pericardial tamponade (discussed later).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

A thorough differential diagnosis of a patient with chest pain is described in Chapter 54. However, the most important initial consideration should always be the deadly causes of chest pain: pericarditis, acute coronary ischemia or infarction, thoracic aortic dissection, and pulmonary embolism. Table 60.1 lists some historical and physical examination features that are helpful in distinguishing among these conditions. Distinction among these causes of chest pain is critical in terms of treatment; patients with pulmonary embolism or myocardial infarction often require treatment with anticoagulants and thrombolytics, medications that can be deadly in patients with acute pericarditis or aortic dissection.

The diagnosis of acute pericarditis is based primarily on the clinical findings. In many cases an electrocardiogram (ECG) is helpful in confirming the diagnosis. Sound knowledge of the ECG findings in patients with acute pericarditis is critical, as well as some findings that help in diagnosing pericarditis versus myocardial infarction (see Table 60.1). Classically, pericarditis evolves through four ECG stages as described in Table 60.2. The first stage of acute pericarditis, characterized by diffuse ST-segment elevation and PR-segment depression or downsloping (Fig. 60.1), is the most common stage encountered in the emergency department (ED). The ST segments should be concave upward; a convex upward (“tombstone”)

| Vital signs | Electrocardiographic findings (See Table 60.2) Early: diffuse ST-segment elevation and PR-segment depression Absence of reciprocal ST-segment depression Sinus tachycardia common; bradycardia and atrioventricular (AV) blocks uncommon | ST-segment elevation or depression typically in an anatomic distribution corresponding to the involved coronary vessel Tachycardia or bradycardia and AV blocks not uncommon | Left ventricular hypertrophy if chronic hypertension present Variable ST-segment or T-wave changes Sinus tachycardia common | Sinus tachycardia common; bradycardia and AV blocks uncommon Large emboli often associated with T-wave inversions, most commonly in right precordial leads and less commonly in inferior leads ST-segment elevation possible but uncommon |
| Friction rub common during course, though less common on initial evaluation | Fourth heart sound is “classic” in cases of cardiac ischemia; third heart sound if heart failure present Occasional pulse deficits Occasional leg swelling or tenderness if embolus originated in the legs |
| Electrocardiographic findings | Chest radiography findings Usually normal; cardiomegaly if large pericardial effusion present | Cardiomegaly if chronic left ventricular hypertrophy present; evidence of heart failure may be present Cardiomegaly common if chronic left ventricular hypertrophy present; wide mediastinum common | Usually normal; most common abnormalities are elevated hemidiaphragm, atelectasis, small pleural effusion |
| Cardiac biomarkers | Levels usually normal; mild elevations not uncommon Elevations typical in myocardial infarction Levels normal | Large emboli occasionally associated with mild elevations in troponin or brain natriuretic peptide |

### Electrocardiographic Stages of Acute Pericarditis

| Stage I | Diffuse ST-segment elevation and PR-segment depression (except in leads V1 and aVR) |
| Stage II | Resolution of the ST-segment and PR-segment changes T-wave flattening in the same leads |
| Stage III | T-wave inversions in the same leads |
| Stage IV | Normalization of electrographic abnormalities |

morphology virtually excludes the diagnosis of pericarditis and rules in acute myocardial infarction. ST-segment depression may be present in leads aVR and V1 in a patient with pericarditis but is unlikely to be present in any of the other 10 leads. In fact, the presence of ST-segment depression in any of the other 10 leads should be considered the “reciprocal” changes of acute myocardial infarction.

These four stages generally progress over the course of days to weeks. The ECG changes in the second and third stages usually occur in the same leads in which abnormalities in the initial stage occurred.

Although the abnormalities noted on an ECG are typically described as “classic” for acute pericarditis, physicians should
Pericarditis, Pericardial Tamponade, and Myocarditis

be aware that these findings are typical only for acute viral pericarditis. Other forms of pericarditis less commonly cause PR-segment depression and occasionally cause less pronounced ST-segment elevation. In these cases, the diagnosis must be based purely on the clinical rather than the ECG findings.

Laboratory studies are rarely helpful in the diagnosis of acute pericarditis. Patients may have an elevated white blood cell count because of pain or infection (or both). Other serum markers of inflammation, including the erythrocyte sedimentation rate and C-reactive protein value, are often elevated, but such elevations are nonspecific. Cardiac biomarkers may be minimally elevated but should not demonstrate the rise and fall typical of myocardial infarction. Chest radiography is also rarely helpful in the diagnosis of acute pericarditis; it is used mainly to evaluate for alternative causes of chest pain (e.g., pneumonia, aortic dissection).

Echocardiography can be useful in distinguishing between acute pericarditis and acute myocardial infarction. Echocardiograms in patients with pericarditis lack the focal wall motion abnormalities that are typical of echocardiograms in those with myocardial infarction. Echocardiography is also useful to look for evidence of pericardial effusion, a potential complication of acute pericarditis (see later). If a large pericardial effusion is present, pericardiocentesis (ultrasonographically guided in a stable patient) can be performed to obtain fluid for testing for infections and cytologic analysis.

**TREATMENT**

Treatment of patients with acute pericarditis should be targeted at the underlying cause. The majority of patients with viral, rheumatologic, posttraumatic, or idiopathic pericarditis are effectively treated with high-dose aspirin (2 to 4 g daily) or nonsteroidal antiinflammatory drugs (NSAIDs). Ibuprofen is effective in most cases and has fewer side effects than other NSAIDs; the pain usually improves significantly within days with ibuprofen therapy. If the patient’s symptoms persist, an alternative NSAID is indicated. Indomethacin is often used for severe cases because of its stronger antiinflammatory effect, although it should be avoided in patients with a history of ischemic heart disease because it may decrease coronary blood flow. Evidence now suggests that addition of colchicine (1.0 to 2.0 mg for the first day and then 0.5 to 1.0 mg/day for 3 months) to the standard regimen is effective in hastening the resolution of acute symptoms and also preventing recurrence rates, regardless of the cause of the pericarditis. Colchicine is also effective in cases of recurrent pericarditis. The use of corticosteroids is generally reserved for recurrent cases of pericarditis that are unresponsive to aspirin or NSAIDs plus colchicine. Initiation of steroids early in the course of first-time pericarditis may actually be an independent risk factor for recurrence.

Patients with bacterial or other nonviral infectious causes of pericarditis should be treated aggressively with antimicrobial therapy. Large infected pericardial effusions require drainage as well. Management of neoplastic causes of pericarditis should be targeted at treating the underlying malignancy. Patients with uremic pericarditis require urgent hemodialysis.

**FOLLOW-UP AND NEXT STEPS IN CARE**

The majority of patients with acute pericarditis can be treated as outpatients, with the symptoms generally resolving within 2 weeks. Outpatient management is suitable for patients with
mild symptoms, hemodynamic stability, and ability to tolerate oral medications. Reasonable indications for admission include fever or suspicion of a bacterial cause of the pericarditis, immunosuppression, pericarditis associated with trauma, presence of a moderate to large pericardial effusion, and hemodynamic instability. A history of active anticoagulant use is generally considered a poor prognostic factor and warrants hospital admission as well.4

**PERICARDIAL TAMPOONADE**

**PATHOPHYSIOLOGY**

Trauma or inflammation of the pericardium can cause fluid to accumulate within the intrapericardial space. Normally, the pericardium is capable of stretching and accommodating 2 L of fluid or more when the fluid accumulates very slowly.1 However, if the fluid accumulates more rapidly than can be accommodated by the distensibility of the pericardium, especially in the case of trauma, in the presence of fibrotic pericardium, or if the volume of pericardial fluid is excessive, significant intrapericardial pressure results and can produce pericardial tamponade.

Pericardial tamponade develops when intrapericardial fluid produces sufficient pressure to compress the cardiac chambers. Compression of the chambers impairs ventricular diastolic filling and stroke volume. Initial compensatory mechanisms, especially tachycardia, may temporarily sustain cardiac output. However, as pericardial fluid continues to increase, the compensatory mechanisms begin to fail, and diminished cardiac output, hypotension, and full cardiovascular collapse ensue.

The typical causes of pericardial tamponade include any disorder that results in acute or chronic pericardial inflammation, as well as conditions in which a patient sustains penetrating trauma to the heart or cardiac surgery. The conditions previously noted to cause pericarditis are common precipitants of pericardial tamponade. The composition of the intrapericardial effusion varies according to the precipitating cause; in bacterial pericarditis, for example, the effusion is often pus, and in cardiac trauma or cardiac surgery, it is often blood and clots. Regardless of the composition of the effusion, the physiology that leads to pericardial tamponade and the immediate treatment are similar.

**PRESENTING SIGNS AND SYMPTOMS**

**CLASSIC**

The typical symptoms associated with a large pericardial effusion are nonspecific. Malaise, generalized weakness, ascites, and edema are common in patients with subacute or chronic effusions as a result of poor cardiac function.5 Many other symptoms are related to compression of adjacent mediastinal structures by the effusion. Dyspnea and cough are common and may be due to displacement or compression of bronchial structures or lung tissue by the effusion. Dyspnea on exertion is common as well and results from impairment of venous return and cardiac output. Patients often report a sense of dysphagia, which is due to esophageal compression. Hiccups may occur as a result of esophageal compression and involvement of the phrenic and vagus nerves. Hoarseness may result from compression of the recurrent laryngeal nerve.6

Physical findings are also often nonspecific. Tachycardia and tachypnea are common. Despite the presence of tachypnea and dyspnea, however, oxygen saturation levels are usually normal because the effusion itself does not impair alveolar air exchange. Lung sounds are generally normal as well. Findings of hypoxia or focal abnormalities on lung examination should suggest a superimposed pulmonary condition or an alternative diagnosis. Fever is common if the underlying cause is infectious. Pericardial friction rubs are reportedly common if the underlying cause is inflammatory, although diminished heart sounds are also frequent because of reduced cardiac function and attenuation of their transmission by the effusion.

When a pericardial effusion produces pericardial tamponade, additional findings are notable. Decreased cardiac function produces hypotension and shock. Jugular venous distention is typically present because of impaired venous return. Pulsus paradoxus (drop in systolic blood pressure of greater than 10 mm Hg during normal inspiration) is also typical, although its presence has limited specificity for pericardial tamponade. Several other conditions that are associated with hypotension or dyspnea (or both) can also produce pulsus paradoxus, including massive pulmonary embolism, hemorrhagic shock, and obstructive lung disease.7 Death is usually preceded by pulseless electrical activity.8

**TYPICAL VARIATIONS**

Although the symptoms and physical findings already noted are common, certain conditions may produce unexpected findings in the presence of pericardial tamponade. Patients who have severe hypothyroidism or uremia or who take atroventricular nodal blocking agents (e.g., calcium channel blockers, beta-blockers, digoxin) may have a relative bradycardia. Jugular venous distention is typical in pericardial tamponade as well, but it is often absent in patients who are hypovolemic or in whom the pericardial tamponade developed very quickly (e.g., after cardiac trauma). Overt hypotension may be absent as well in patients with a history of severe antecedent hypertension.9

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

A complete differential diagnosis of hypotension and shock is beyond the scope of this chapter. However, the emergency physician (EP) should always consider other typical causes of hypotension, especially those that similarly produce jugular venous distension: massive pulmonary embolism, large left ventricular myocardial infarction with cardiogenic shock, right ventricular myocardial infarction, acute aortic or mitral valve insufficiency, and superior vena cava syndrome.

The primary means of diagnosing pericardial tamponade is via two-dimensional echocardiography. A pericardial effusion is easily seen in most patients on subcostal or parasternal views (Fig. 60.2). An echo-free space should be visible through the cardiac cycle when the pericardial effusion is at least 25 mL.10 The presence of a pericardial effusion in combination with hypotension and echocardiographic
Pericarditis, Pericardial Tamponade, and Myocarditis

EVIDENCE OF EARLY DIASTOLIC RIGHT VENTRICULAR COLLAPSE AND LATE DIASTOLIC RIGHT ATRIAL COLLAPSE IS DIAGNOSTIC OF PERICARDIAL TAMPONADE. IN APPROXIMATELY 25% OF CASES, THE LEFT ATRIUM ALSO DEMONSTRATES COLLAPSE, A VERY SPECIFIC SIGN OF TAMPO- NADE. THE LEFT VENTRICLE RARELY DEMONSTRATES COLLAPSE EXCEPT IN SPECIFIC CONDITIONS SUCH AS LOCALIZED POSTOPERATIVE TAMPO- NADE. OTHER ECHOCARDIOGRAPHIC FINDINGS THAT MAY BE FOUND IN PATIENTS WITH PERICARDIAL TAMPO- NADE ARE A DILATED INFERIOR VENA CAVA WITHOUT INSPIRATORY COLLAPSE AND BEAT-TO-BEAT SWINGING OF THE HEART WITHIN THE PERICARDIAL FLUID (WHEN THE EFFUSION IS LARGE).

OTHER IMAGING STUDIES CAN BE HELPFUL IN EVALUATING THESE PATIENTS AS WELL. COMPUTED TOMOGRAPHY (CT) AND MAGNETIC RESONANCE IMAGING ARE VERY ACCURATE IN DETECTING PERICARDIAL EFFUSIONS, IN ADDITION TO DIAGNOSING ALTERNATIVE CONDITIONS. HOWEVER, THEY SHOULD NOT BE USED IN PATIENTS WITH BORDERLINE OR OVERT HEMODYNAMIC INSTABILITY BECAUSE OF THE NEED TO REMOVE SUCH PATIENTS FROM THE ED FOR THE PROCEDURES. CHEST RADIOGRAPHY IS PRIMARY USED TO EVALUATE THE PATIENT FOR ALTERNATIVE DIAGNOSES AS WELL, SUCH AS PNEUMONIA OR PULMONARY EDEMA.

THE ECG CAN BE HELPFUL IN THE DIAGNOSIS OF LARGE PERICARDIAL EFFUSIONS. THE MOST COMMON ABNORMALITY IS TACHYCARDIA, ESPECIALLY IN THE PRESENCE OF TAMPONADE. LOW VOLTAGE IS COMMON AS WELL AND IS CAUSED BY ATTENUATION OF THE ELECTRICAL IMPULSE AS IT PASSES THROUGH THE EFFUSION BEFORE REACHING THE ECG ELECTRODES. ALTHOUGH LOW VOLTAGE IS NONSPECIFIC, THE PRESENCE OF NEW LOW VOLTAGE (IN COMPARISON WITH PREVIOUS ECGS) IS MUCH MORE SPECIFIC FOR LARGE PERICARDIAL EFFUSIONS.

THE THIRD “CLASSIC” ECG ABNORMALITY IS ELECTRICAL ALTERNANS. ELECTRICAL ALTERNANS REFERS TO BEAT-TO-BEAT VARIATION IN AMPLITUDES OF THE ECG COMPLEXES AND IS ATTRIBUTED TO “SWINGING” OF THE HEART BACK AND FORTH WITHIN THE PERICARDIAL FLUID. ELECTRICAL ALTERNANS IS PRESENT IN LESS THAN ONE THIRD OF CASES OF PERICARDIAL TAMPO- NADE. ALTHOUGH NONE OF THESE THREE FINDINGS INDIVIDUALLY IS COMPLETELY DIAGNOSTIC OF LARGE PERICARDIAL EFFUSIONS, THE COMBINATION OF ALL THREE IS VERY HIGHLY SPECIFIC.

Treatment

INITIAL MANAGEMENT OF PATIENTS WITH PERICARDIAL TAMPO- NADE SHOULD FOCUS ON THE TYPICAL ABCS OF RESUSCITATION (AIRWAY, BREATHING, CIRCULATION). CERTAIN CAVEATS SHOULD BE MADE, HOWEVER. ALTHOUGH THE PRIMARY PATHOPHYSIOLOGIC ABNORMALITY UNDERLYING HEMODYNAMIC COMPROMISE IN PATIENTS WITH PERICARDIAL TAMPO- NADE IS VENTRICULAR FILLING, THE BENEFIT OF VOLUME INFUSION TO IMPROVE FILLING IS CONTROVERSIAL. ANIMAL STUDIES HAVE SHOWN VARIABLE RESULTS WITH RESPECT TO THE HEMODYNAMIC BENEFIT OF VOLUME INFUSION, WHICH MAY IMPROVE SYSTEMIC PERFUSION ONLY IN PATIENTS WITH HYPOVOLÉMIA.

Strong supportive data in humans are lacking, however. In patients with traumatic pericardial tamponade, large-volume infusions may actually precipitate further deterioration. Strong evidence supporting specific inotropic agents is lacking as well, although theoretically agents that reduce the elevated vascular resistance, such as dobutamine and milrinone, would seem ideal. Mechanical ventilation should generally be avoided except in patients with respiratory failure; the positive airway pressure associated with mechanical ventilation decreases venous return and cardiac output.

TREATMENT

Initial management of patients with pericardial tamponade should focus on the typical ABCs of resuscitation (airway, breathing, circulation). Certain caveats should be made, however. Although the primary pathophysiologic abnormality underlying hemodynamic compromise in patients with pericardial tamponade is ventricular filling, the benefit of volume infusion to improve filling is controversial. Animal studies have shown variable results with respect to the hemodynamic benefit of volume infusion, which may improve systemic perfusion only in patients with hypovolemia. Strong supportive data in humans are lacking, however. In patients with traumatic pericardial tamponade, large-volume infusions may actually precipitate further deterioration.
